

Fig. 27-21 Presurgical dental decompensation in the sagittal plane for class II and class III malocclusion. A goal of presurgical orthodontic management is to maximally decompensate the anterior dentition from pretreatment (*blue*) to presurgical (*red*) incisor position. As a consequence, the occlusion becomes worse. This allows the surgeon to reposition the skeleton so that when surgery is complete, the incisors are in an appropriate position with respect to their dental bases.

Anteroposterior decompensation involves correction of the maxillary and mandibular incisors (Figs. 27-20 and 27-21). In the typical class II malocclusion, the maxillary incisors are retroclined, and the mandibular incisors are proclined to allow a functional bite as a natural compensation to the skeletal deformity. Thus the decompensation involves orthodontically uprighting the proclined mandibular incisors. This may require removal of the mandibular first molars to relieve crowding if there is insufficient arch length to accommodate retraction and alignment of the incisors. In the maxilla, the opposite occurs. Decompensation of the maxillary incisors by proclination relieves any crowding typically without the need for extraction. Decompensation of class III malocclusion occurs in the reverse pattern.

In the vertical plane, dental decompensation of the anterior dentition depends on two factors: the amount of dental display of the maxillary incisors in relation to the upper lip and the lower anterior facial height (Fig. 27-22). When there is excessive dental display with gingival show in skeletal anterior open bite deformities, the extruded maxillary teeth that compensate for the open bite can be intruded orthodontically to a limited extent to level it in a single occlusal plane, with maxillary skeletal impaction surgery accomplishing most of the correction. Orthodontic correction alone will yield an unstable result. Frequently the posterior teeth may be in a significantly different occlusal plane from the anterior dentition. In such cases, if segmental maxillary repositioning is needed, the presurgical orthodontic treatment correspondingly involves segmental leveling in two different planes. In such cases, root diversion is needed to allow interdental osteotomies for a multisegmented LeFort I procedure.

In patients with a deep anterior incisor overbite, the decision of whether to level the occlusal plane depends on the lower facial height. When the lower facial height is normal, the deep bite is corrected by presurgically intruding the incisors. In contrast, when the lower facial height is

Fig. 27-23 Presurgical orthodontic management. The dentition has been aligned within the dental arches and decompensated to allow skeletal correction.

Fig. 27-24 Presurgical orthodontic management. **A**, Pretreatment. **B**, Orthodontic treatment without advancement. **C**, The maxillary-mandibular arches are well coordinated for surgery to ensure stability.

reduced, as in deep class II skeletal conditions, the arches are not leveled presurgically but instead after mandibular advancement. By maintaining the curve of Spee, the mandibular advancement will result in a “tripod” occlusion, with the incisors anteriorly and the molars posteriorly on either side. This will allow a natural increase in the lower facial height. The resulting lateral open bite will then be closed by extruding the mandibular premolars and leveling the curve of Spee. If the occlusal plane was instead leveled presurgically, correction of the lower facial height will then require osseous genioplasty.

In the transverse plane, the maxillary and mandibular dental arches need to be coordinated with the postsurgical occlusion. Because of the relative transverse arch width discrepancy with class II and class III malocclusions, the dentoalveolar compensations must be removed. As with removal of the sagittal compensations, the arch width discrepancy is worsened. Depending on the discrepancy, the options are transpalatal orthodontic expansion with or without surgical assistance versus segmental maxillary osteotomies at the time of the formal orthognathic surgical procedure. Expansion may be accomplished orthodontically alone with a palatal expansion device if the midpalatal suture is open; otherwise, this may require surgical assistance with an osteotomy. When interdental osteotomies are needed, orthodontic root divergence is necessary. Minor width discrepancies may be acceptable with some degree of orthodontic compensation and can frequently be corrected postoperatively.

If a mandibular osteotomy, such as sagittal split, is contemplated, it is generally wise to have the mandibular third molars extracted well in advance (typically 8 to 12 months) to minimize the risk of an unfavorable osteotomy and to allow internal fixation.⁵⁸ During this phase, the dentition is orthodontically aligned within the respective dental arches, the curve of Spee is leveled, and the anterior dentition is decompensated. This is done independently within each of the dental arches with no attempt to correct the occlusion. Because of this, the malocclusion is frequently made worse, and patients must be made aware of this. However, the maxillary and mandibular dentition are coordinated with each other as if the surgery had been accomplished with the use of dental casts, which can be freely manipulated. Progressive dental models are obtained throughout the orthodontic treatment, and when they can be hand coordinated with stable occlusion, then planning for surgery can begin (Figs. 27-23 and 27-24). If segmental osteotomies are planned, the dentition must be prepared accordingly. If osteotomies are not through planned extraction sites, interdental space must then be orthodontically prepared with the roots widely divergent to prevent injury, with the space favorably closed at the time of surgery. Periapical and panorex films should be used to evaluate the space for osteotomies. Segmental dental casts will confirm the readiness for surgery.

The orthodontist will then typically replace the archwire with a heavy rectangular wire ligated to the orthodontic brackets and surgical hooks to permit intraoperative and postoperative maxillary-mandibular fixation. At the time of surgery, there should be no active dental movement, and the orthodontic wire should remain passive. If segmental osteotomies are planned, the archwire should likewise be segmented before surgery. This presurgical phase typically varies from 6 to 18 months, depending on what needs to be accomplished to maximize the final surgical stability at the occlusal level.

Surgical Phase

The surgical phase consists of three components: surgical planning, the operation, and the immediate recovery phase.

Surgical Planning

The surgical phase begins approximately 4 weeks before the surgical date. This starts with a clinical reevaluation of the patient and obtaining presurgical planning records.^{27,59,60} The clinical

focus should include reconfirming with the patient whether a maxillary, mandibular, or double jaw procedure is to be performed. Dental midlines in relation to each other and in relation to the facial midline should be carefully recorded. Orthodontic movement of dentition alone will subtly alter facial features such as lip posture and the amount of dental display, and such changes need to be taken into account when planning the final skeletal movement. Key points should be discussed with the patient, such as the amount of dental display, appearance of the smile, changes in the nasal-columellar contour, alar base and nasal tip position, chin position, and any residual asymmetry that inevitably becomes more noticeable by the patient after the surgery.

If only a single-jaw procedure is planned, conventional cephalometric analysis and an acrylic splint fabrication from presurgical dental casts mounted on a simple hinge or Galetti-type articulator are sufficient to execute the surgical procedure (Fig. 27-25). The splint is needed to intra-operatively index the relative position of the maxillary dental arch to the mandibular dental arch. For upper jaw surgery only, the vertical position of the maxilla is primarily determined by the desired dental display and the appearance of the smile. With lower surgery alone, the mandible

Fig. 27-25 A, Model surgery and splint fabrication for a single-jaw procedure with a hinge-type articulator (Galetti). This is independent of the skull base, because only the relative position is needed of the jaw that is being operated on to the jaw that is not. B, Facebow transfer and model surgery for a two-jaw procedure in which the relation of the jaws to the skull base (Frankfort horizontal) is needed to appropriately position the maxilla and mandible.

is positioned spatially by the fixed maxillary dental arch. Routine conventional 2D cephalometric analysis of the initial position and the predicted position is sufficient to guide the surgeon.^{26,61-65}

However, currently, with the exception of the simplest of orthognathic cases (single jaw with relative facial symmetry), we develop a composite 3D virtual model of the patient by fusing the 3D data sets of the CBCT scan of the facial skeleton with the digitally scanned dental models and the 3D surface color and texture images of the patient (3D photos). The composite model is developed in the digital environment with one of a number of virtual surgical planning (VSP) software systems that are now commercially available. The software allows the surgeon to simulate the various surgical procedures by tailoring the osteotomies and repositioning the various skeletal elements to the patient's specific deformity.

The ability to visualize the surgical simulation in 3D allows the surgeon to consider the asymmetry in the three orthogonal planes and to visualize osteotomy gaps and bone interferences that are likely to become evident during the operative procedure. Currently for us, 3D VSP has replaced the traditional approach of using facebow mounted dental casts and model surgery because of the inherent inaccuracies and limitations when applying it to patients with congenital deformities and facial asymmetries that require two-jaw surgery. Moreover, the “model” surgery in the virtual environment of the digital computer using the patient's facial skeleton is a more realistic and more relevant simulation for the surgeon⁶⁶⁻⁷¹ (Fig. 27-26).

Fig. 27-26 VSP (model surgery) is based on the use of a composite model of the patient that “fuses” the 3D data sets of the CBCT scan, the dental models, and 3D photographic images. This replaces the model surgery using facebow mounted plaster/stone dental casts shown in Fig. 27-25, B.

A practical approach to VSP is to first correct the facial asymmetry in the frontal plane. This will then convert a complex case of asymmetry into a more straightforward and familiar orthognathic procedure that focuses on correcting the sagittal (lateral) discrepancy only (Fig. 27-27).

Even though the CBCT provides a 3D view of the facial skeleton, for analysis and correction of the dentofacial deformity, it is best to begin initially from the lateral view, with the standard lateral cephalometric view extracted from the CBCT. Thus our typical two-jaw sequence in simulation using VSP software is outlined in Table 27-2.

Steps 5, 6, and 7 establish frontal symmetry. Step 8 is the conventional and more familiar orthognathic 2D planning and sagittal (profile) correction. With the maxilla in the optimal position, steps 10, 11, and 12 reposition the mandible to the maxilla. Step 13 may require repeating steps 7 through 12. Correcting the yaw of the maxilla and mandible can be difficult. Step 15 repositions the chin to the desired position.

Table 27-2 Steps in 3D Computer-Assisted Virtual Surgical Planning of Orthognathic Surgery

Steps		Environment
1	Collect data from clinical assessment: 2D and 3D photographs, CBCT, dental models	Surgical records
2	Create virtual composite model of the patient	Virtual environment
3	Assign skeletal and soft tissue landmarks for cephalometric analysis in 3D and 2D	VSP software
4	Perform LeFort I osteotomy tailored to the patient's skeletal deformity	
5	Correct the maxillary asymmetry in the frontal plane "roll"	
6	Correct the maxillary dental midline to the facial skeletal midline "translation"	
7	Correct the maxillary asymmetry in the transverse plane "yaw"	
8	Reposition the maxilla in the sagittal plane to the desired position (dental display, smile, occlusal plane, incisor angulation); 2D cephalometrics	
9	Design an intermediate surgical splint based on the simulation of the upper jaw surgery first	Physical environment CAD-CAM 3D fabrication
10	Perform BSSO of the mandible	Virtual environment
11	Reposition the mandible to coordinate with the final desired occlusion	VSP software
12	Reposition the proximal ramal components to a more appropriate position relative to the mandibular body	
13	Assess, and if needed, correct the mandibular yaw; this may require repeating the sequence of steps 7-12	
14	Design the final surgical splint based on the lower jaw surgery second	Physical environment CAD-CAM 3D fabrication
15	Perform osseous genioplasty	Virtual environment VSP software

When repositioning of both jaws is planned, an intermediate splint (step 7), in addition to the final splint (step 11), is fabricated with 3D digital printing. These replace the traditional acrylic splint laboratory fabrication with facebow mounted plaster/stone model surgery. These splints then allow accurate intraoperative positioning of the maxilla and mandibular dentoalveolar segments. In addition, the surgical splints are important to ensure postoperative stability when the maxillary and mandibular arches are insufficiently coordinated for maximal intercuspal interdigitation.

Surgery

Surgery is then executed with the use of surgical splints to guide the intraoperative repositioning of the maxillary and mandibular segments. The surgical steps follow that of the VSP simulation. The details of the surgical technique are described later in a separate section.

Postoperative Recovery

In the immediate postoperative period, airway management is of primary concern, and patients require close monitoring. Most patients are discharged from the hospital after an overnight stay for hemodynamic and airway monitoring. The discharge instructions that are reviewed with the patient and family focus on controlling pain or discomfort primarily with the use of nonsteroidal antiinflammatory agents, supplemented by the occasional use of narcotic medications, cold compresses for edema and comfort, maintaining oral and nasal hygiene, a diet ranging from pureed to mechanically soft foods with maintenance of calories, proteins, and vitamins, and the importance of early ambulation and a return to normal daily activities.

A panorex/cephalometric radiograph in the early postoperative period is obtained to ensure that the condyles are in their appropriate positions. If the condyles are significantly displaced with a postoperative occlusion not anticipated, the patient will likely need to return to surgery and osteosynthesis will be redone.

Postoperative surgical practices vary, depending on the surgeon's preferences and the stability that the surgeon believes is obtained at the time of surgery. This has varied from maintenance of maxillary-mandibular fixation with wire to using only guiding dental elastics for varying periods, typically 2 to 6 weeks. Within this period the surgical splint, if used, is removed, and patients are instructed regarding how to increase the maxillary-mandibular range of motion that has been limited until now and to gradually return to their usual diet. Early function of the temporomandibular joint with continual assessment of the occlusion will allow the surgeon and orthodontist to use dental elastics to guide the occlusion, because internal fixation is "semirigid." Patients are followed closely, and if there is any change in occlusion, elastics can be applied accordingly in the appropriate vector to guide the occlusion until bony healing is complete.

Our experience has been that most patients recover by 2 weeks after surgery, and by the third week have returned to school and work, with appropriate limitations.

Postsurgical Orthodontic Management

The postsurgical orthodontic phase typically begins 4 to 8 weeks after surgery. Patients then return to the orthodontist for completion of the dental alignment with the relative position of the skeletal bases in their final position. Any remaining interdental spaces are closed, and the dentition is brought into an optimal intercusp relationship. This phase typically lasts for approximately 6 to 12 months and formally ends with the removal of the orthodontic braces; patients are then instructed on the use of a retainer to maintain long-term stability. Photographs, radiographic studies, and dental models are obtained on debanding of the orthodontic braces and at 1 year after completion of treatment. Ideally, when possible, patients should have yearly follow-up examinations for an extended period to assess long-term results.

Prosthodontic and Restorative Phase

The final phase includes placement of dental implants, prosthetic and periodontal treatment, and any dental restorations to improve the final dental aesthetics. After the dentoskeletal correction is completed, plastic surgery soft tissue procedures can be considered to improve the final overall facial aesthetics.⁷²

SURGICAL DETAILS

The elements of the facial skeleton can be repositioned, redefining the face through various well-established osteotomies: (1) LeFort I osteotomy, (2) LeFort II osteotomy, (3) LeFort III osteotomy, (4) maxillary segmental osteotomies, (5) sagittal split osteotomy of the mandibular ramus, (6) vertical ramal osteotomy, (7) inverted L and C osteotomies, (8) mandibular body segmental osteotomies, and (9) mandibular symphysis osteotomies.^{1,73-78} The vast majority of maxillofacial deformities can be managed with three basic osteotomies: (1) the midface with the LeFort type I osteotomy, (2) the lower face with sagittal split ramal osteotomy of the mandible, and (3) horizontal osteotomy of the symphysis of the chin.

Midface

Various osteotomies are used to correct midfacial deformities; the choice of a particular procedure depends on the specific deformity. The LeFort osteotomies of today are named after the three classic lines of weakness of the facial skeleton described by René LeFort in 1901. Complete craniofacial disjunction by the LeFort III osteotomy allows the surgeon to alter the orbital position and volume, the zygomatic projection, and the position of the nasal root; it also alters the frontonasal angle and lengthens the nose and position of the maxilla. The LeFort II osteotomy allows the surgeon to alter the nasomaxillary projection without altering the orbital volume and zygomatic projection. The LeFort I osteotomy also allows correction primarily at the occlusal level affecting the upper lip position, the nasal tip and alar base region, and the columellar-labial angle without altering the orbitozygomatic region. Nevertheless, it is important to remember that these standard LeFort osteotomies must be frequently modified to address the specific clinical situation. For example, the standard LeFort I osteotomy must be modified to include a portion of the body of the zygoma when the lower maxillary deficiency is accompanied by inadequate zygomatic projection, but the orbit itself does not need to be altered as it would be in a LeFort III osteotomy. LeFort II and III osteotomies are generally part of the treatment plan in the major craniofacial dysostosis syndromes and are discussed elsewhere in this book. For most midfacial maxillofacial deformities encountered, the LeFort I osteotomy and its variations are adequate.

Deformities of the maxilla can occur in all three planes, and in many patients will frequently occur simultaneously in multiple planes. Even when the primary deformity is in the mandible, including a maxillary repositioning osteotomy, in addition to mandibular surgery, will in many cases improve the postoperative skeletal stability and aesthetic outcome. With its technical ease and dependability of outcome, the LeFort I osteotomy has become the principal procedure used to resolve virtually the full range of anteroposterior, vertical, transverse, and rotational deformities that surgeons may see. Once sectioned, the maxillary dentoalveolar segment can be repositioned to correct occlusal coordination virtually in any direction as a single unit, and when needed, it can be further subsectioned to differentially move the individual elements in all three planes. However, the multiple-segment LeFort I osteotomy increases the complexity and risks of the surgical procedure.

With maxillary osteotomies, an understanding of the vascular blood supply to the mobilized maxilla is crucial (Fig. 27-28). The arterial blood supply to the maxilla is derived from the following four primary sources: (1) the descending palatine branch of the maxillary artery, (2) the ascending palatine branch of the facial artery, (3) the anterior branch of the ascending pharyngeal artery from the external carotid, and (4) the alveolar branches of the maxillary artery. With complete mobilization of the maxilla, the descending palatine vessels are frequently disrupted, and the mobilized maxilla derives its vascularity from the remaining sources, primarily the ascending palatine and pharyngeal vessels.⁷⁹⁻⁸¹

LeFort I Surgical Details

An external reference mark is made by tattooing the medial canthus with methylene blue dye, and the vertical distance is measured to the maxillary archwire by the lateral incisor. (Alternatively, some surgeons prefer to use a K-wire placed at the nasion or an internal bony reference mark with a drill hole before the osteotomy.) This measurement is used to vertically position the maxilla (Fig. 27-29).

Exposure to the midfacial facial skeleton is accomplished through an intraoral labial-buccal incision above the attached gingiva from first molar to first molar, leaving an adequate mucosal edge (a minimum of 5 to 8 cm) to facilitate final closure (Fig. 27-30).

The subperiosteal dissection is then directed superiorly exposing the anterior maxillary wall, identifying the inferior orbital foramen, exposing the lateral zygomatic-maxillary buttress, the body of the zygoma, and the anterior portion of the zygomatic arch.

Fig. 27-29 LeFort I procedure. **A**, Nasotracheal intubation is secured at the septum and scalp without distorting the ala. **B** and **C**, Infiltration with a local vasoconstricting agent. **D**, Methylene blue is used to mark the medial canthus for vertical reference.

Fig. 27-30 **A** and **B**, The incision should be made well above the attached gingiva, sparing the frenulum, from premolar to premolar. **C** and **D**, The incision should then be made deeper along the inferior edge to avoid entering the nasal mucosa centrally.

Fig. 27-31 A, Subperiosteal dissection. B, Exposure of the supraorbital nerve. C, Area of skeletal exposure. D, Exposure of the pterygopalatine region.

Fig. 27-32 A and B, Exposure of the piriform aperture. C, Exposure of the lateral nasal wall inferior to the turbinate and the nasal floor to the junction of the hard and soft palate. D, Exposure and separation of the anterior nasal spine from the septum.

The superior exposure must be sufficient to accommodate the fixation plates. The dissection continues posteriorly to the pterygopalatine region. Dissection is then directed medially to expose the nasomaxillary buttress, piriform aperture, and anterior nasal spine. The intranasal dissection is then carried out exposing the nasal floor, the lateral nasal wall below the inferior turbinate, and medially the septum and vomer. The dissection should continue posteriorly to the junction of the hard and soft palate (Figs. 27-31 and 27-32).

With the skeletal exposure complete, the planned osteotomy is marked noting the tooth root apices and infraorbital foramen. There are many variations on the standard LeFort osteotomy, and as previously stated, each osteotomy must be tailored to the individual patient (Figs. 27-33 and 27-34). A reciprocating saw is used to complete the horizontal maxillary osteotomies, proceeding from the lateral nasal wall across the anterior maxillary wall and through the posterior lateral maxillary wall. If needed, the reciprocating saw can be redirected from lateral to medial to facilitate completion of the osteotomy.

Fig. 27-33 LeFort I procedure. **A**, The osteotomy is marked and planned based on the patient's deformity. **B**, Conventional LeFort I osteotomy. **C** and **D**, Modified LeFort I osteotomy, including varying components of the maxilla and zygoma.

Fig. 27-34 A, Conventional LeFort I osteotomy. B, Modified LeFort I osteotomy. The difference between these two procedures is shown. By varying the osteotomy design and angulation, the anterior vertical height and dental display can be controlled. With a conventional LeFort I osteotomy, increasing the anterior vertical height requires increasing the osteotomy gap and the need for bone grafting to ensure stability.

Fig. 27-35 A and B, The septum is separated from the vomer from the anterior nasal spine to the posterior nasal spine. C and D, The pterygoid plate is separated from the maxillary-palatine bone.

The nasal septum and vomer are then separated from the maxillary crest with a septal osteotome that is directed downward and posteriorly. Alternately, the septal osteotomy can be accomplished with a reciprocating saw that is directed away from the side with the nasal intubation to avoid transecting the nasotracheal tube. Finally, a curved osteotome is used to separate the pterygoid plate from the maxillary tuberosity. The pterygopalatine disjunction osteotomy should be positioned parallel to the occlusal plane and below the maxillary osteotomy to avoid injuring the internal maxillary artery. A finger placed behind the maxillary tuberosity can easily verify the separation. Some surgeons prefer to use an oscillating saw instead of the osteotome (see Figs. 27-33 through 27-36).

After the osteotomy is completed, the maxilla is downfractured (Fig. 27-37). This can typically be achieved with digital pressure alone by placing the thumbs at the base of the piriform aperture. If there is any significant resistance, it is preferable to revisit the osteotomy sites with the reciprocating saw and an osteotome and then immediately proceed with Rowe disimpaction forceps. The use of significant force to accomplish the downfracturing can lead to unfavorable fractures. The areas that are typically incomplete are the posterior aspect of the lateral nasal walls and the pterygopalatine disjunction. As the maxilla is mobilized inferiorly, any adherent nasal floor mucosa should be simultaneously elevated. Once the downfracture is completed, the maxilla is mobilized from side to side and then anteriorly in the sagittal direction with the aid of Tessier retromaxillary levers or Rowe forceps and releasing any adherent soft tissue from the posterior aspect behind the tuberosity. The maxilla should be so completely mobilized that it can be passively placed in its final position with a pair of forceps (Figs. 27-38 and 27-39).

With the maxilla downfractured and mobilized, a prefabricated occlusal splint is then ligated to the maxillary archwire, and the maxilla and mandible are placed in maxillary-mandibular fixation either with wire or dental elastics. The maxillary-mandibular complex is allowed to rotate within its arc of rotation, with the mandibular condyle seated in its glenoid fossa. The maxilla is then brought into the desired anterior vertical position based on the amount of dental display desired from the preoperative analysis. This is confirmed by the vertical measurement from the previously marked reference point. Any areas of bony interference should be removed, along with the nasal septum, to prevent septal buckling. The removal of bone should be done selectively to

Fig. 27-37 A reciprocating saw is used to section the lateral nasal wall and anterior maxillary wall through the sinus and well above the dental roots.

Fig. 27-38 After the downfracture is completed, Rowe and retromaxillary forceps can be used to further mobilize the maxilla.

Fig. 27-39 The maxilla should be mobilized so that forceps can easily reposition the maxilla alone without tension. Frequently the soft tissue may need to be further freed.

allow maximal bony contact for stability. When the maxilla is in the desired position, it is stabilized with plates and screws at the medial and lateral buttresses. The maxillary-mandibular fixation is then released, and the occlusion is verified so that the mandible passively closes directly into the splint without repositioning. If there is any question that the condyle was not properly seated at the time of fixation, the osteosynthesis must be redone. If there is significant inferior maxillary repositioning, either autologous bone or alloplastic hydroxyapatite should be used for interpositional buttress grafts (Figs. 27-40 through 27-43).

After the maxilla is rigidly fixed and the occlusion is satisfactory, the operative wounds are closed. The septum should be fixed in the midline and an alar cinch suture placed for a wide-flaring ala if needed. At the time the vestibular incision is closed, cheiloplasty with V-Y advancement or any number of variations can be considered.

Fig. 27-40 A, A surgical splint fabricated from the model surgery is wired to the maxillary dental archwire. B, The maxilla and mandible are then placed in fixation with dental elastics.

Fig. 27-41 The vertical height is measured from the medial canthus marked with methylene blue to the incisor archwire before the maxilla is downfractured. With the condyles seated within the glenoid fossa, the vertical position of the maxilla is determined based on the desired anterior facial height and dental display. A, Increase in vertical length and incisor show. B, Decrease in anterior vertical length with less incisor show (impaction).

Fig. 27-43 A, The maxillary-mandibular interdental fixation is removed, and the occlusion is checked to confirm whether the mandible directly comes into the splint with the condyles seated. B and C, If the condyles are not properly seated at the time of fixation, the malocclusion will become readily evident (anterior open bite). The plates will need to be removed, and the maxilla and mandible are placed in elastic fixation. The maxilla is replated with the condyles seated within the glenoid fossa.

Lower Face

For the lower face, various osteotomies are used to correct mandibular deformities; which one to use depends on the particular deformity. Today the sagittal split ramal osteotomy is the workhorse for correcting the vast majority of cases of mandibular retrognathism and prognathism. In extreme cases of mandibular prognathism, some surgeons prefer the intraoral vertical osteotomy (IVO) or inverted-L osteotomy. In cases of mandibular advancement when the mandibular rami are hypoplastic and cannot be sagittally split, the inverted-L and C osteotomy with bone grafts are preferred. Deformities of the chin can exist independent of mandibular deformities and can be abnormally proportioned in and of themselves without occlusal involvement. Although alloplastic chin implants have been most commonly used for correction of minimal sagittal chin deficiencies, the horizontal osteotomy of the symphysis (osseous genioplasty) is a far more versatile procedure. The chin can be repositioned in multiple planes, allowing correction of significant sagittal and vertical deformities whether of deficiency (microgenia) or excess (macrogenia), along with asymmetrical conditions.

With mandibular osteotomies, the surgeon must be cognizant of the course of the inferior alveolar nerve from its entrance at the mandibular foramen on the medial aspect of the ramus to its emergence from the mental foramen between the first and second premolars to minimize neurosensory deficits. Regarding the vertical position, the mandibular foramen typically lies approximately 8 cm inferior to the lingula, and the lingula itself is approximately 5 cm above the occlusal plane. Using the sigmoid notch as a reference point, the foramen is approximately 20 cm inferior. Regarding the anterior to posterior relationship, the foramen is located 20 mm from the anterior mandibular ramal border, a depth that is approximately two thirds of the total mandibular ramal width. The canal then courses within the mandible, measuring 2 to 2.5 mm in diameter. Its lowest point from the inferior mandibular border is in the region of the first and second molars, approximately 7.5 cm, before it continues anterior and superior to its emergence from the mental foramen, where it is approximately 8 mm from the inferior border. At the mental foramen, the canal extends caudally before emerging. Regarding the transverse position of the canal within the mandible, the canal is most superficial in the region of the third molar, approximately 2 mm from the buccal plate. In the region of the first molar, it is 4 mm from the buccal plate.^{82,83}

Sagittal Split Osteotomy of the Mandibular Ramus

The ascending ramus is palpated, and the mucovestibular incision is placed well lateral to the posterior dentition to allow an adequate medial mucosal edge for final closure. The incision typically begins approximately 1 to 2 cm above the occlusal plane and continues to the region of the first molar (Fig. 27-44).

The incision then continues through the periosteum, exposing the lateral border of the posterior body, angle, and ascending ramus. The inferior mandibular border is exposed with an inferior border stripper so that a channel retractor can be easily placed. The anterior ramal border is partially stripped of the temporalis muscle, and a retractor is placed superiorly onto the coronoid process. The medial portion of the ramus is elevated with a curved periosteal elevator beginning well above the occlusal plane proceeding from superior to inferior so that the inferior alveolar neurovascular bundle is safely reflected medially. In elevating the medial ramus, care must be taken to remain subperiosteal and to recall the anatomic topography with the lingula and the relationship of the mandibular foramen (Fig. 27-45).

With the exposure complete, a medial ramus retractor or a curved elevator is then placed to protect the neurovascular bundle. The horizontal osteotomy of the medial ramus is made first with either a Lindemann side-cutting burr or a reciprocating saw starting well above and posterior to the mandibular foramen. The osteotomy is deepened to approximately half the thickness

Fig. 27-44 BSSO of the mandible. **A**, The incision is made well lateral to the attached gingiva in the molar region. **B**, The mandibular ramus is exposed in the subperiosteal plane. **C**, The lateral ramus, angle, and body are exposed. **D**, The inferior border is exposed.

Fig. 27-45 **A** and **B**, A channel retractor is placed to support the mandible. **C** and **D**, The anterior ramal border and coronoid process are exposed to the insertion of the temporalis muscle.

of the ramus and obliquely made so that the osteotomy can be continued inferiorly. A reciprocating saw is used to continue the osteotomy laterally along the external oblique ridge to the region between the first and second molars. The tip of the saw should only penetrate the anterior cortex, and the osteotomy should be placed as far lateral as possible to protect the nerve. The saw is then repositioned to make the vertical osteotomy through the buccal cortex, typically between the second and first molars. Care must be taken to ensure that the vertical osteotomy continues through the inferior mandibular border to the medial lingual cortex. The remainder of the osteotomy is completed with a series of osteotomes, beginning from mesial to distal, approaching the horizontal osteotomy of the mandible. The osteotomes are directed laterally toward the buccal cortex to avoid transecting the inferior alveolar nerve. A three-point spreader can be placed to begin the separation, which can be completed with an osteotome at points of resistance. The course of the inferior alveolar nerve should be entirely within the distal tooth-bearing segment. If it is not, the nerve must be mobilized from the proximal segment. The separation must be complete so that the mesial tooth-bearing segment will move independent of the distal condylar segment and can be repositioned into final occlusion with little resistance. The osteotomy on the contralateral side is then carried out (Figs. 27-46 through 27-49).

Fig. 27-46 A, A medial ramus retractor is placed to protect the nerve. B-D, A horizontal osteotomy is made with a Lindemann burr, or a reciprocating saw can be used.

Fig. 27-47 A reciprocating saw is then used along the external oblique ridge and continued to the region of the first and second molars, where a vertical osteotomy is made. The vertical osteotomy can be made with either a Lindemann burr or a reciprocating saw.

Fig. 27-48 BSSO of the mandible. **A**, With a series of osteotomes, the corticotomy is converted to an osteotomy. The osteotomes should be directed laterally along the medial surface of the lateral or buccal cortex to minimize injury to the nerve. **B**, A ramal spreader is then introduced, and the medial and lateral cortices are separated, complete with the nerve within the medial component. **C** and **D**, The lateral ramal component should be completely freed and independent of the distal dental arch.

Fig. 27-49 BSSO of the mandible. The mandible is then either advanced or set back by placing it within the prefabricated surgical splint and maxillary-mandibular dental fixation.

Fig. 27-50 BSSO of the mandible. The repositioned elements are then fixed either with positional screws placed through a transbuccal approach or with titanium plates through an intraoral approach.

The mesial (distal) tooth-bearing segment is placed in maxillary-mandibular fixation with a prefabricated occlusal splint ligated to the maxillary archwire. The condylar distal (proximal) segment is seated within the glenoid fossa. Fixation is typically obtained by placing three bicortical screws in an inverted-L pattern or with an inferior border monocortical plate and a single positional bicortical screw. Fixation can be entirely transoral with a contraangle drill and screw-driver system or a transbuccal trocar approach. It is important to note that the bicortical screws are positional screws used to “loosely” approximate the bony segments and are not lag screws. If the screws are tightened down, the proximal segment may be laterally displaced out of the glenoid fossa, and there is some risk of a “crush” injury to the nerve. The maxillary-mandibular fixation is released and the occlusion is checked. If the occlusion is unacceptable, the fixation must be removed and the segments repositioned. If the occlusion is satisfactory, the wounds are then approximated (Fig. 27-50).

Osseous Genioplasty

A labial mucosa incision, typically from canine to canine, is made well above the attached gingiva to allow closure. The mentalis muscle is partially transected from its insertion, and a subperiosteal dissection is carried out. The dissection over the pogonion must be limited in scope so that the dissection continues below the mental foramen and as far lateral as possible to the inferior mandibular border in the region of the second premolar and first molar (Fig. 27-51).

With the exposure complete, the osteotomy is marked a minimum of 5 to 6 mm below the tooth root apices and similarly below the mental foramen. The surgeon must remember that the canine length is approximately 30 mm and that the mental foramen extends caudally before it emerges.

Fig. 27-51 Genioplasty. **A**, The incision is made inferior to the attached gingiva. **B**, The mentalis muscle is then divided, leaving an adequate cuff of muscle for reattachment at the time of closure. **C** and **D**, The symphysis is exposed in the subperiosteal plane.

Fig. 27-52 A, The area of exposure is limited to leave a muscular attachment at the symphysis (vascular pedicled genioplasty). B, The osteotomy is made as posterior as technically possible, 5 to 6 mm below the mental foramen. C and D, The chin can be repositioned in all three planes to correct the sagittal, vertical, and transverse components of the chin deformity.

Fig. 27-53 A, The midline is marked. B, The planned osteotomy is then marked well below the dental roots and mental foramen. C and D, The osteotomy is made with a reciprocating saw.

Fig. 27-54 A, The symphysis is mobilized. B and C, Two methods of plate fixation. D, The mentalis muscle is approximated at the time of mucosal closure.

The osteotomy can be varied, depending on the deformity and the planned correction. The midline is scored with an oscillating saw, and the symphyseal osteotomy is made with a reciprocating saw.

If a double osteotomy is planned either for a step advancement or a wedge resection, the distal or inferiorly marked osteotomy should be made first. The lateral inferior border osteotomies must be completed carefully with the reciprocating saw. The inferior segment should easily separate if the osteotomy is complete (Figs. 27-52 and 27-53).

The inferior pedicled osseous segment is then mobilized to the desired position and fixed with plates and screws. A step deformity is typically palpable at the inferior border mandibular osteotomy sites. Although the deformity will become less significant with remodeling, this can be contoured with a guarded rasp (Fig. 27-54). The wound is then closed by approximating the mentalis muscle and overlying mucosa.

Sequencing the Intraoperative Procedure

The sequence of operative procedures is based on the preoperative planning and model surgery. If a single jaw is being repositioned, a final splint is then used to guide the occlusion of the jaw being moved relative to the remaining jaw. If both maxillary and mandibular repositioning osteotomies are planned, an intermediate splint is then used to guide the movement of one jaw relative to the other jaw. Although the maxilla is typically repositioned first, followed by the mandible, the sequence can be reversed with the appropriate intermediate splint at the time of the model surgery. The remaining jaw is then repositioned based on the final splint. After the maxilla and mandible are in their final positions, the chin is assessed, and an osseous genioplasty is performed if necessary.

MANAGEMENT OF DEVELOPMENTAL DENTOFACIAL DEFORMITIES

Mandibular Deficiency

Patients with mandibular deficiency clinically present with a convex facial profile (Figs. 27-55 and 27-56). Although the aesthetic soft tissue analysis of the upper and middle thirds of the face is within an acceptable norm, the lower third of the face is retruded. Along with it, the lower lip is everted with a deep labial mental crease, and because there is lip incompetence, mentalis muscle strain is seen with lip closure. The neck length may be short with an obtuse cervical mental angle, and redundancy of the soft tissue may be present. Dental examination will show an Angle class II malocclusion that is further subdivided into Angle division 1 or Angle division 2 based on the incisor relationship. In Angle class II division 1, the maxillary incisor angulation is within an acceptable range and there is significant overjet. In Angle class II division 2, the maxillary incisors are retroclined, giving the appearance of less overjet, and in addition, there is an associated deep bite and an overaccentuated curve of Spee, resulting in decreased lower facial height. In comparison, the lower facial height is normal with division 1 malocclusion.

Because the position of the incisors dictates the degree of surgical movement, the orthodontist positions the maxillary and mandibular incisors in the “ideal” position in both the anteroposterior and vertical planes. Failure to adequately decompensate limits the surgical correction and aesthetic outcome. When there is crowding of the lower dental arch, it is frequently necessary to extract the lower first bicusps and retract the anterior dentition. This allows maximal mandibular advancement. In comparison, maxillary crowding in many circumstances can be managed by transpalatal expansion or, when severe, extraction of the upper second bicusps to minimize retraction of the maxillary incisors so as not to limit the mandibular advancement.

Routine leveling of the occlusal plane to obtain arch compatibility needs to be individualized, depending on the severity of the curve of Spee. If the curve of Spee is orthodontically leveled before surgery, this is accomplished by intrusion of the mandibular incisors and will further adversely decrease the lower facial height in patients with class II division 2 malocclusion. It is preferable to skeletally advance the mandible to incisor class I before leveling to maximally increase the lower facial height. The resultant lateral open bite is then closed orthodontically in the postsurgical phase by extrusion of the premolars. With only three-point contact (anterior and the two posterior molar regions), a surgical splint is needed to ensure stability. The greater the lower facial height, the more likely that the leveling should be done by incisor intrusion before surgery. With the exception of the patient with a severe curve of Spee and decreased lower facial height discussed previously, establishing maximal arch compatibility before surgery is important to ensure immediate postoperative stability.

Skeletal advancement is achieved by BSSO of the mandible as described previously. The postsurgical management includes the use of class II elastics to override proprioception and guide the new occlusion in the immediate postoperative period. Orthodontic management then finalizes the coordination of the dental arches by definitive leveling of the curve of Spee, closure of any spaces, and correction of any minor crossbites.

Fig. 27-55 Mandibular deficiency. Mandibular advancement was achieved by BSSO of the ramus.

Fig. 27-56 Mandibular advancement combined with an osseous genioplasty. The patient subsequently underwent a rhinoplasty.

Mandibular Excess (Prognathism)

Patients who have mandibular excess (prognathism) have a concave facial profile where the deformity is primarily isolated to the lower third (Fig. 27-57). However, the vast majority of patients also have some degree of midfacial skeletal deficiency. It is estimated that only 20% to 25% of patients have isolated or “true” prognathism. A number of patients also have overclosure of the mandible, further accentuating the prognathism and midfacial deficiency. Dental examination will show a class III malocclusion with lingually inclined mandibular incisors.

Presurgical orthodontic preparation includes decompensating the mandibular incisors to the “ideal” position; however, in many patients this is limited by the thin alveolar process of the symphyseal region and the thinly attached gingiva. Any transverse width discrepancy must be addressed by orthodontic expansion of the maxillary palate or surgical assistance before formally correcting the class III sagittal discrepancy.

The surgeon's options for correcting the class III skeleton are either the IVO or BSSO of the ramus. The IVO is technically simpler with a lower incidence of inferior alveolar nerve in-

Fig. 27-57 Mandibular excess corrected by BSSO with a setback. In the early recovery phase, the patient is maintained in class III occlusion with the use of dental elastics for neuromuscular adaptation.

jury and is less likely to adversely affect the biomechanics of the temporomandibular joint compared with the BSSO. In addition, when large rotational movement of the mandible is required to correct asymmetry, the IVO is preferred by many on the side that moves posteriorly, whereas on the advancement side, a BSSO is carried out. The disadvantage of the IVO is the prolonged 4- to 6-week period of maxillary-mandibular fixation, because rigid fixation is not possible and it is only suited for setback. However, in most circumstances of class III patients requiring less than 10 mm setback, the BSSO with internal fixation is preferred, because it allows early function. When BSSO setback is carried out, overcorrection by approximately 2 mm should be planned in the surgical splint fabrication because of the postsurgical rebound that occurs as the condyle repositions in the glenoid fossa and the relapsing forces that occur as a result of decreasing the intraoral volumetric space. Class III elastics are required for extended periods with postsurgical orthodontic finalization. For minimal setbacks, instead of a BSSO, it is frequently preferable to correct the class III malocclusion with maxillary advancement from an aesthetic standpoint alone, because the skeletal expansion allows “filling” of the soft tissue envelope. For large setbacks, similarly combining midfacial skeletal advancement will limit the amount of mandibular setback required, and a BSSO rather than an IVO can be accomplished. Present-day aesthetics suggest that the isolated mandibular setback is rarely required.

Sagittal Maxillary Deficiency

Because of the similarity in clinical presentation, maxillary anteroposterior sagittal deficiency has often been diagnosed solely as mandibular excess (prognathism), and a mandibular setback procedure is planned (Figs. 27-58 and 27-59). However, in many circumstances the deformity also includes the midface, and instead of a mandibular setback alone, the patient is better served by a midfacial skeletal advancement either solely or in combination with mandibular surgery. Both have a class III skeletal pattern. Clinically, these patients present with a concave facial profile, deficiency of the maxilla that may extend to involve the zygoma, paranasal deficiency with a narrow alar base, an acute nasolabial angle, a short upper lip, a retrusive upper lip with a thin vermilion, and in many circumstances an accompanying lack of dental display (vertical deficiency). Dental characteristics include a class III molar and canine relationship, maxillary dental crowding with canines blocked out of the dental arches, and in many instances deficient transverse palatal arch width (posterior lingual crossbite), proclined maxillary incisors, and mandibular incisors that are either in the normal position or retroclined.

The orthodontist then eliminates the dental compensations, establishes an ideal incisor position, and coordinates the maxillary and mandibular dental arches. If there is an absolute transverse width discrepancy, this requires palatal expansion as a two-segment LeFort I osteotomy with simultaneous correction of the sagittal discrepancy. The roots of the central incisors then need to be deviated to safely perform the interdental osteotomy. In many patients it is preferable to stage the orthognathic surgery by first correcting the transverse width discrepancy by orthodontic expansion, which may require surgical assistance (surgically assisted rapid palatal expansion), and subsequently correcting the sagittal discrepancy as a single-unit LeFort I procedure to maximize skeletal stability.

With maxillary crowding and the need for incisor retraction, the decision to extract the first or second premolar is based on the extent of crowding and the degree of incisor decompensation needed. When the advancement of the mandibular incisors is limited by lack of attached gingiva and/or minimal alveolar bony support, a mandibular second premolar extraction may be necessary to provide the necessary space. In most circumstances, the maxillary first premolars are extracted, and when needed in both arches, it is combined with extraction of the mandibular second premolars as the most common extraction pattern.

The surgeon then corrects the midfacial skeletal deficiency with a LeFort I osteotomy that is tailored to address the patient's particular deformity. The traditional LeFort I osteotomy is inclined inferiorly from anterior to posterior. Thus when the maxilla is advanced along this incline plane, the sagittal deficiency is corrected. This results in an undesirable decrease in the anterior facial vertical height, and in many cases there is a need to correct the associated vertical deficiency (lack of dental display). The maxillary segment must then be rotated, which results in a significant bony gap and the need for a bone graft. If instead the osteotomy is designed in a reverse plane

Fig. 27-58 Midfacial skeletal deficiency in a patient with a facial cleft corrected in two stages by reconstructing the cleft alveolar defect with an iliac bone graft followed by a modified LeFort I advancement.

that is inclined superiorly from anterior to posterior, then as the maxilla is advanced to correct the sagittal deficiency, the vertical deficiency is corrected by correspondingly increasing the anterior vertical height. This results in sufficient bony contact without the need for a bone graft in most cases and a stable advancement with titanium plate fixation alone. By varying the inclination of the osteotomy plane, the anterior vertical height can be corrected. When there is severe vertical deficiency, distraction osteogenesis remains the most stable means of achieving significant vertical lengthening. In addition, many patients with maxillary deficiency will also have malar deficiency (flat malar prominence), and the traditional LeFort I osteotomy will not address this, because the osteotomy courses inferior to the ascending lateral zygomatic buttress. The LeFort I osteotomy is then modified to include the body of the zygoma (retruded malar eminence) and, to a varying extent, the zygomatic arch as first described by Obwegeser in 1969 and now known as the “quadrangular” LeFort I osteotomy popularized by Keller and Sather in 1990.^{1,78,84} With these variations, the osteotomy of the posterior lateral maxilla extending superiorly along the posterior aspect of the body of the zygoma is made with some degree of difficulty, and frequently the osteotomy may not be complete and the downfracture may be difficult.

Fig. 27-59 Maxillary deficiency with mandibular overclosure corrected with a modified LeFort I advancement.

Vertical Maxillary Excess

Patients with vertical maxillary excess or long-face syndrome will have an increase in lower facial height and, with clockwise rotation of the mandible, a convex facial profile. The chin is vertically long and retrusive (Figs. 27-60 and 27-61). Bilabial lip incompetence (increased interlabial gap) is present, and mentalis strain occurs with attempted lip closure. There is excessive dental display on repose and a “gummy” smile. The lower lip appears protrusive without support of the upper dentition. The alar base is frequently narrow, the paranasal regions are deficient, and there is lack of malar projection in many patients. Intraoral examination reveals an anterior open-bite deformity in most of these patients, a high-arched palate with a V-shaped transversely narrow maxilla, and dentition in palatal crossbite. Although the occlusal relationship is class II in most cases, class I and class III can occur with vertical maxillary excess. Downward and posterior rotation of the mandible (clockwise rotation of the mandibular plane) resulting from excessive vertical maxillary growth will make the associated mandibular deficiency appear worse and the mandibular excess not as severe. Although an anterior open bite is the usual presentation, in patients with vertical maxillary excess and a deep bite, the lower facial height may not appear to be increased, and excessive dental display is camouflaged by the lower lip.

Orthodontic management involves elimination of dental compensations and leveling of the mandibular arch. In patients in whom the open bite is severe and there is an excessive reverse curve in the maxillary arch, it is preferable to level the arch in segments with root deviations to allow interdental osteotomies and surgical leveling with a three-segment LeFort I procedure. When the vertical discrepancies are minimal, the arch can be leveled in a single plane, and the open bite can be corrected by a differential posteroanterior impaction single-unit LeFort I procedure. The open bite should not be closed orthodontically to minimize recurrence. Relief of dental crowding and transverse palatal expansion (surgically assisted) should be addressed before definitive orthognathic surgery.

Fig. 27-60 This patient with vertical maxillary excess underwent presurgical orthodontic treatment. The transverse maxillary deficiency was corrected in the first stage through transpalatal expansion.

In most patients, correction of vertical maxillary excess requires double jaw surgery: differential LeFort I impaction of the maxilla either as a single segment or multisegment with mandibular BSSO advancement and a genioplasty. It is rare that LeFort I impaction, with or without a genioplasty with reliance on autorotation of the mandible, will result in a stable occlusion and satisfactory aesthetic outcome. Prediction cephalometric tracings are beneficial to assess the need for concomitant mandibular surgery. Although preoperative planning will approximate the amount of bone that needs to be resected to achieve the desired dental display based on clinical examination and desired final aesthetics, en bloc removal of the predetermined amount will likely leave large gaps between bony surfaces with superior repositioning of the maxilla. To avoid this, less bone should be resected initially and the dental display should then be adjusted intraoperatively by selectively and sequentially removing bone from points of bony interferences with the use of rongeurs as the maxillary-mandibular complex with an intermediate splint is rotated counter-clockwise. This will frequently result in slotted joints that lock the mobilized maxilla into its base similar to “Lincoln logs.” Failure to remove adequate bone from the posterior maxilla and medial maxillary walls will prevent unrestrained superior repositioning of the maxilla, and frequently the condyle is brought out of the fossa with rotation of the complex. This will become evident when the maxillary-mandibular fixation is released and the mandible fails to rotate appropriately into

Fig. 27-61 Presurgical planning involving cephalometric analysis (A and B), facebow transfer (C), and model surgery (D and E).

Continued

Fig. 27-61, cont'd F, Intraoperative view showing resection of the maxilla for vertical impaction. G-J, Postoperative outcome with finalization of orthodontic occlusion.

the intermediate splint. In addition, with impaction of the maxilla, the base of the septum and vomer should be trimmed, and inferior turbinectomies may need to be carried out to minimize significant septal buckling and airway compromise from decreased nasal cross-sectional area.

Undesirable changes can occur with maxillary impaction that alter the alar base width, the columellar-labial angle, nasal tip projection, and lip contour. These must be assessed before surgery and addressed intraoperatively with alar cinch sutures and contouring the nasal piriform to adjust the alar vestibule, V-Y closure of the lip to alter the lip contour, and an osteotomy that repositions or contours the anterior nasal spine to control the nasal labial angle and upper lip length. Soft tissue alterations are not necessarily always predictable and must be discussed with the patient because secondary surgery involving the lip and nose may be needed to achieve the patient's aesthetic goals.

Facial Skeletal Asymmetry

Patients may also have facial skeletal asymmetry as a result of congenital deformities (hemifacial microsomia), developmental problems (unilateral condylar hyperplasia), or trauma to the condylar region (Fig. 27-62). The principles outlined earlier apply, although correction of such dentofacial deformities is typically more complex, because there is asymmetry in all three planes. Model surgery must be accurate, and CBCT scans will often be needed to guide the surgical planning. In addition to the skeletal asymmetry, many patients will have soft tissue components that require correction after the skeletal framework is in a more symmetrical position.

Fig. 27-62 Patient with facial skeletal asymmetry (unilateral left condylar hyperplasia) corrected by asymmetrical LeFort I osteotomy, BSSO, and genioplasty.

MANAGEMENT OF CLEFT-RELATED DENTOFACIAL DEFORMITIES

Orthognathic surgery to correct dentofacial deformities in patients with facial clefts is a more complex undertaking, because such patients present with not only skeletal considerations, but the soft tissue component also plays a significant role in the management and outcome. Although the goal of orthognathic surgery in all patients is to achieve ideal occlusion, in patients with clefts, this often requires performing multiple-segment osteotomies and overcoming the restricting forces of the soft tissue–scar tissue impediment to maxillary advancement. Furthermore, the surgeon must take into account poor bone stock. All these factors must be carefully considered and accurately evaluated during the preoperative planning stages. A comprehensive strategy that addresses each of these variables is of paramount importance for achieving an excellent result.

Approximately 25% to 30% of patients who have undergone surgical correction of cleft lip/palate develop midface retrusion severe enough to require orthognathic correction. Maxillary hypoplasia resulting in class III malocclusion is the typical deformity seen in this patient population. The cause of maxillary hypoplasia is twofold. Evidence shows that inelastic scar tissue from the original palatoplasty restricts facial growth and suggests an intrinsic midfacial growth deficiency unrelated to surgery (that is, it is an inherent component of the congenital anomaly).⁸⁵ Although mild class III malocclusions may be treated with orthodontics alone, orthognathic surgery is needed to ideally correct a more severe class III dentofacial deformity.

Preoperative Considerations

The chance of a favorable surgical outcome is optimized if presurgical planning is performed in conjunction with a cleft/craniofacial team. Speech pathologists play an integral role in evaluating the velopharyngeal mechanism and the potential effects that maxillary advancement may have on speech nasality and articulation. Preoperative videonasoscopy has been shown to yield information that can aid in predicting postoperative hypernasality.

Patients with a cleft lip and/or palate anomaly have several anatomic differences compared with unaffected patients. The maxilla is typically deficient in both the anteroposterior and vertical dimensions. Because midface retrusion can be significant, it frequently appears that the mandible is prognathic, but true mandibular prognathia is rare. The apparent prognathia is relative and a result of the maxillary deficiency. Also, because of lesser segment collapse, the dental midline is often deviated toward the cleft side, and this must be taken into consideration for proper midline repositioning.

Despite having undergone alveolar bone grafting, many of these patients have deficient or missing bone in the region of the alveolus. Persistent palatal fistulas may also be present. The lateral incisor is frequently missing in these patients, and closure of this space must be taken into account at the time of treatment planning. Various options for prosthetic reconstruction of this edentulous space are described in Chapter 29. If a large fistula is present in the alveolus, modifications of the LeFort I procedure can be performed to facilitate a tension-free alveolar closure. These are discussed in the following section.

Surgical Aspects

Orthognathic surgery for patients with cleft lip/palate is similar to that for patients without clefts, except for several important modifications necessary to maintain blood supply and assist in associated primary palatal alveolar residual cleft oronasolabial fistula closure.

In patients with unilateral cleft lip, the standard incision can be made with little jeopardy to the premaxillary blood supply (Fig. 27-63, *A*). Each side of the cleft requires an incision made similar to that of an alveolar bone graft incision (Fig. 27-63, *B*). This allows two-layer closure of the palatal and nasal mucosa. If supplemental bone grafting is required at this time, harvested bone can be placed into the alveolar gap after fixation has been applied. If a wide fistula is present, the maxillary segments can be compressed to reduce the size of the alveolar space (Fig. 27-63, *C*). This maneuver ensures that the soft tissue closure is under minimal tension, and the chance of fistula closure is optimized. Compressing the maxillary segments or congenital absence of the lateral incisor can place the canine adjacent to the central incisor. Although this may not be a great aesthetic concern, a restorative dentist can fabricate a prosthetic crown for the canine to make it look like a lateral incisor.

With patients who have bilateral clefts, care must be taken to avoid making the vestibular incision across the premaxilla. The premaxillary blood supply is from the vomer and buccal mucosa. Because the vomer will be split, most of the blood flow to the premaxilla will be from the premaxillary buccal mucosa. A circumvestibular incision that violates this mucosa can severely

Fig. 27-63 *A*, For patients with a unilateral cleft lip, the incision is made similar to a standard LeFort I osteotomy, except an alveolar dissection is used if supplemental bone grafting or fistula closure is necessary. *B*, The LeFort osteotomy allows compression of the maxillary segments if necessary to close a preexisting fistula. *C*, Fistula repairs are easier after compression of the segments and exposure of nasal and palatal tissue.

jeopardize the blood supply of the premaxillary segment. To minimize the risk of complications, the incision is stopped just lateral to the alveolar cleft on each side (Fig. 27-64, *A*). Reflection of the mucosa from the premaxilla is minimized to preserve the blood supply. The osteotomy of the premaxillary segment is made from a posterior approach just anterior to the incisive foramen to allow mobilization of the segment without violation of the buccal mucosa (Fig. 27-64, *B*). Similar to a unilateral cleft maxilla, residual fistulas and inadequate alveolar bone may be present. If either is identified, it can be corrected by a two-layer mucosal closure and bone grafting into the alveolar defect (Fig. 27-64, *C*). If large gaps are present that may jeopardize fistula closure, the segments can be compressed at the alveolar gaps to reduce the tension of the repair (Fig. 27-64, *D*). Postoperative orthodontics and prosthetic restorations of the teeth can correct most postoperative dental aesthetic irregularities.

Fig. 27-64 *A*, For patients with a bilateral cleft, care is taken to avoid incisions across the premaxilla. *B*, The premaxillary osteotomy is complicated from a posterior approach. *C*, Fistula repairs or supplemental bone grafting can be performed at this time. *D*, Compression of the maxillary segments can be performed if wide fistulas are present.

Velopharyngeal Dysfunction and Speech

It is generally accepted that velopharyngeal dysfunction (VPD) in patients with cleft lip/palate is caused by a malalignment or shortening of the palatal musculature, skeletal growth and development, and/or surgical sequelae that can lead to abnormal structural relationships. Alveolar fistulas and a constricted arch can contribute to resonance disorders (hypernasality or hyponasality) or articulation defects (errors in formation of consonants). Given the intricate attachment of the maxilla to the muscular apparatus of the velum, it follows that moving the maxilla can change velopharyngeal function.

Janulewicz et al⁸⁶ performed a retrospective study of the change in velopharyngeal function in cleft lip/palate patients who underwent maxillary advancement with or without a mandibular setback procedure over a 21-year period. As summarized in Table 27-3, their study showed a decline in competent velopharyngeal function (42% to 18%) and an increase in both borderline insufficiency (9% to 22%) and complete VPD (13% to 20%). The authors also noted that the quality of speech declined, as evidenced by the increase in overall objective speech score from 2.46 to 4.24 (the higher the score, the worse the speech). In contrast, the authors noted that articulation defects improved, although the improvements did not achieve statistical significance. Preoperatively, 84% (46 patients) had at least one articulation defect compared with 73% (40 patients) postoperatively.

Other studies have shown similar results or no change in VPD function. Both Watzke et al⁸⁷ and more recently Phillips et al⁸⁸ have shown that the extent of anteroposterior maxilla movement is unrelated to velopharyngeal functional deterioration and is not a useful predictor. In a study of 25 patients (16 unilateral complete and 9 bilateral complete cleft lips/palates), the authors showed that all patients who had perceived hypernasal speech before their surgery had hypernasality after advancement. Furthermore, 9 of 12 patients (75%) who had preoperative

Table 27-3 Comparison of Preoperative and Postoperative Speech Variables

Total Number of Patients: 54	Preoperative Evaluation Percentage (n)	Postoperative Evaluation Percentage (n)
VP function: competent	42 (23)	18 (10)
VP function: borderline competent	36 (20)	40 (22)
VP function: borderline incompetent	9 (5)	22 (12)
VP function: complete VPD	13 (7)	20 (11)
Normal nasality	40 (22)	40 (22)
Mild hypernasality	18 (10)	29 (16)
Moderate hypernasality	4 (2)	15 (8)
Severe hypernasality	4 (2)	2 (1)
Hyponasality	33 (18)	15 (8)
Reduced sibilant IOAP	26 (14)	35 (19)
Reduced fricative IOAP	16 (9)	26 (14)
Reduced plosive IOAP	6 (3)	22 (12)
Anterior dentition errors	64 (35)	47 (26)
Mean speech score	2.46	4.24

IOAP, Intraoral air pressure; VP, velopharyngeal; VPD, velopharyngeal dysfunction.

nasopharyngoscopy showing borderline or inadequate closure developed VPD postoperatively. Furthermore, they found that nasoendoscopy adds little to perceived speech testing in its ability to predict which patients develop VPD after maxillary advancement. Based on these results, the researchers concluded that preoperative assessment can predict postoperative speech and velopharyngeal function and that nasoendoscopy plays a minor role in the preoperative evaluation of patients without fistulas and borderline or hypernasal speech.

Because elements of speech are linked to hard and soft tissue relationships, advancing the maxilla would seemingly affect articulation; however, data from multiple studies appear to be inconsistent. Witzel and Munro⁸⁹ showed that improving skeletal malocclusions with orthognathic surgery improved articulation, especially for the production of sibilant sounds. In contrast, Dalston and Vig⁹⁰ found no improvement in articulation after surgery.

Thus it appears that although a positive effect on articulation might be achieved by orthognathic surgery, it might be at the expense of velopharyngeal function. Because there is uncertainty about how much maxillary advancement could affect speech, the physician should discuss possible changes in speech with the patient and family before surgery.

Skeletal Stability and Relapse With Conventional Cleft Orthognathic Surgery

Posnick⁹¹ performed a retrospective study evaluating relapse in patients who had undergone orthognathic surgery for cleft lip/palate between 1987 and 1990. The author found that there was no significant difference in outcome between patients who had maxillary surgery alone and those who had surgery on both jaws. Furthermore, the outcome did not vary significantly with the type of autologous bone graft used or the segmentalization of the osteotomy.

All 35 patients included in the study had a modified LeFort I maxillary osteotomy with varied degrees of horizontal advancement, transverse arch widening, and vertical change. Eleven of the 35 patients (32%) also required mandibular surgery consisting of BSSO.⁹¹ In 13 of 35 patients (37%), a pharyngoplasty was in place at the time of the LeFort I osteotomy.⁹¹ The mean horizontal advancement achieved for the group was 6.9 ± 2.6 mm at 1 week; 5.3 ± 2.7 mm was maintained 1 year later (mean relapse 1.6 mm). In 11 of 35 patients (32%), the relapse was less than 1.0 mm. For the 13 patients (37%) who had pharyngoplasty at the time of the LeFort I osteotomy, the mean horizontal advancement was 8.2 mm immediately after surgery and 6.5 mm 1 year later. The stability of the vertical displacement was also evaluated. No maxillary vertical change was necessary in 12 of 35 patients (34%). The mean vertical displacement of the maxilla in patients who underwent vertical repositioning was 2.1 ± 2.4 mm at 1 week; 1.7 ± 2.0 mm was maintained 1 year later. The author concluded that neither horizontal nor vertical relapse was related to the extent of movement. The overjet seen on cephalometric radiographs 1 year postoperatively was maintained in all patients, whereas a positive overbite was maintained in only 30 of 35 patients (85%).⁹¹

Other investigators have found a correlation between relapse and the degree of advancement.⁹² To identify factors associated with relapse after orthognathic surgery in patients with cleft lip/palate, Hirano and Suzuki⁹³ performed a retrospective study on 58 patients with cleft lip/palate who underwent orthognathic surgery over a 10-year period. They identified the following factors related to relapse:

1. Horizontal advancement. The mean horizontal relapse was 24.1% of the mean advancement. There was significant correlation between extent of relapse and advancement. The authors report that complete surgical mobilization of the maxilla is important for preventing relapse.

2. Vertical displacement inferior positioning. The mean inferior vertical elongation was 3 mm, with a relapse of 2.1 mm. The authors recommended a 2 mm overcorrection with inferior positioning of the maxilla.
3. Rotation, clockwise or counterclockwise. Most surgical rotation was lost, and relapse was seen with both clockwise and counterclockwise rotations. The authors recommended overcorrection to mitigate the effects of relapse.
4. Type of cleft. Orthognathic surgery for a bilateral cleft was more likely to result in relapse. The authors attributed this greater likelihood to increased scarring of palatal tissues and multiple missing teeth.
5. Previous alveolar bone grafting. Although studies have reported the value of alveolar bone grafting for establishing advancement stability and minimizing relapse, Hirano and Suzuki⁹³ found no association between alveolar bone grafting and the rate of relapse in patients with unilateral cleft lip/palate.
6. Number of missing teeth. No correlation was found between the number of missing teeth and relapse, although the authors stressed that multiple missing teeth can compromise the stability of the occlusion.
7. Type of orthognathic surgery. There was no difference in the relapse rate between patients who underwent maxillary surgery alone and those who underwent two-jaw surgery.

Role of Distractional Osteogenesis in Midfacial Advancement

Patients with mild-to-moderate maxillary hypoplasia are good candidates for traditional or conventional orthognathic surgery; however, those with severe maxillary retrusion (greater than 10 mm) are prone to a significant amount of relapse. Several studies have shown that patients with severe maxillary deficiency have less predictable results and a higher rate of relapse.⁸⁻¹² Furthermore, the need for revision and prolonged orthodontics is higher. This subset of patients might benefit from advancement by distraction osteogenesis.

Distraction osteogenesis at the LeFort I level has been recommended for the early treatment of severe midface deficiency for patients in the mixed dentition stage. Cho and Kyung⁹⁴ conducted a retrospective study to evaluate the long-term stability of maxillary distraction osteogenesis with a rigid external device, based on a 7-year experience. In their study, the mean distraction length was 13.6 mm immediately after distraction (Table 27-4). However, at the 6-month follow-up, the mean distraction length was 10.8 mm and 10.4 mm at the 1- to 6-year follow-up. Based on their results, the mean postoperative relapse rate was 23% at 1 to 6 years. Preoperatively, the mean SNA angle was 78.5 degrees, and immediately after distraction it was 90.7 degrees. Six months postoperatively, the mean SNA angle was 87.2 degrees and 86.9 degrees 1 to 5 years postoperatively. These results show that most relapse occurs in the first 6 months. The relapse rate increased

Table 27-4 External Distraction Outcomes

	Immediate Postoperative Outcome	6 Months Postoperatively	1 to 6 years Postoperatively
Mean length	13.6 mm	10.8 mm	10.4 mm
Mean relapse rate	N/A	20.7%	23.0%

up to 6 months after distraction and was not statistically significant between 1 year and 6 years after distraction. They concluded that a 20% to 30% overcorrection is required with maxillary advancement to compensate for the relapse.

Polley and Figueroa⁹⁵ studied 16 patients between 5 and 25 years of age who underwent correction of maxillary hypoplasia with a rigid external distraction device. The patients underwent distraction followed by a 2- to 3-week rigid retention phase and achieved a mean advancement of 11.7 mm. The authors reported no relapse at the 4- and 12-month follow-up intervals. In later reports they attributed decreased facial convexity at the 1-year follow-up to a combination of maxillary resorption, forward mandibular growth, and closed rotation of the mandible.

The benefits of rigid external distraction are the versatility and flexibility of both the amount and direction of the distraction process. With a skull-anchored, external headframe distractor attached to an orthodontic splint, precise control of the maxillary segments can be achieved with accurate, consistent, and unlimited distraction. However, the only aspect of this system that is rigid is the halo, which attaches to the head. The maxilla is not rigidly held in its postoperative position after advancement. Patients are allowed to function with an osteotomized maxilla. Although studies have not shown a higher incidence of nonunion with this concept, it contradicts principles of fracture management.

Kumar et al⁹⁶ compared the correction of severe maxillary retrusion using distraction via internal devices with conventional orthognathic surgery. Fifty-one patients with cleft lip/palate were divided into three groups based on the extent of maxillary retrusion and type of orthognathic treatment: group 1 (n = 20): mild-to-moderate deficiency (less than 10 mm) treated with a conventional orthognathic procedure; group 2 (n = 11): severe deficiency (10 mm or more) treated with conventional orthognathic surgery; and group 3 (n = 20): severe deficiency (10 mm or more) treated with distraction osteogenesis.

The results showed that group 1 patients had a mean advancement of 7 mm (Table 27-5). In this group, all patients finished with a class I occlusion and had no complications, relapse, or revisions. Group 2 patients had a mean horizontal advancement of 11 mm. In this group, one patient (9%) had a class III malocclusion postoperatively, and six of 11 patients (55%) had class III malocclusion at follow-up. Seven of 11 (64%) developed relapse, and five of 11 (45%) underwent reoperation. Group 3 patients had a mean advancement of 25 mm. At follow-up, a 15% relapse rate was observed (3 of 20 patients).

Although group 2 patients underwent less advancement than group 3 patients, group 2 patients had a higher relapse rate. The authors suggested that the gradual skeletal advancement offered by distraction provides greater advancement with less relapse in patients with severe maxillary deficiency. When conventional orthognathic surgery was used for group 2 patients, the lack of gradual expansion affected the surrounding soft tissue scars, which most likely contributed to the high relapse rates seen in this group. The authors also suggested that gradual advancement with distraction osteogenesis allows the LeFort I segment to move a greater distance and remain stable in its new location because of slow scar tissue adaptation.

The effects on speech were compared between distraction and orthognathic procedures. Patients who underwent distraction had better speech scores and less VPD than acutely advanced patients. Furthermore, nasal endoscopy in selected patients showed that those who underwent distraction had fewer structural problems with oronasal closure than patients in the orthognathic group. This study indicates that for patients with severe maxillary deficiency, LeFort I distraction may offer better results than traditional orthognathic surgery.

Orthognathic surgery is typically performed after skeletal growth is complete so that the patient's mandible does not outgrow the surgical correction achieved by maxillary advancement. Delaying the procedure also avoids the risk of injuring tooth buds or roots of the permanent dentition, if the teeth have not erupted beyond the site of the planned osteotomy. The benefit of

the traditional orthognathic surgical procedure is precise control of the occlusion and application of rigid fixation to secure the maxilla's position.

Unlike the one-stage orthognathic procedure, advancement by distraction requires at least two operative procedures, and the patient must also endure the appliance for 8 to 12 weeks. The LeFort I osteotomy for distraction is essentially the same as that performed for traditional orthognathic surgery, and thus the risk of injury to tooth buds and the potential to outgrow the correction are the same. Also, if distraction is performed at an earlier age, the risks are higher than with traditional orthognathic surgery. Final control of occlusion is not as precise with internal distraction, and mobility is present after external distraction. Surgical distraction must offer clear benefits over traditional orthognathic surgery to be considered for treatment. Indications for the use of maxillary distraction over traditional orthognathic surgery are reduced rates of relapse and VPD. With an extremely deficient maxilla for which the surgeon is not comfortable with his or her ability to achieve adequate advancement with orthognathic techniques, distraction allows a slow adaptation of the scarred palatal tissues, possibly reducing relapse. In addition, distraction has been shown to have a lower postoperative incidence of VPD.^{95,96}

Unless distraction achieves perfect occlusion without relapse and mandibular overgrowth, the patient will still require subsequent orthognathic surgery. In this situation the question arises regarding whether the long process of distraction osteogenesis followed by an orthognathic procedure offers any advantages over two-stage LeFort I osteotomies. We think that although distraction osteogenesis is a valuable tool, its indications must be carefully weighed against those of traditional orthognathic techniques.

Table 27-5 Cleft Orthognathic Outcome

	Group I: Mild-to-Moderate Deficiency (mm)	Group II: Severe Deficiency (mm)	Group III: Severe Deficiency (mm)
Deficiency	≤10	≥10	≥10
Number of patients	20	11	20
Type of procedure	Orthognathic surgery	Orthognathic surgery	Internal distraction
Mean advancement	7	11	25
ΔX preoperative to postoperative	5	7.22	16.5
ΔX postoperative to follow-up	4.9	5.8	16.1
ΔY preoperative to postoperative	−0.5	−0.4	−1.1
ΔY postoperative to follow-up	−0.5	−0.2	−1.0
Other Data			
Number of relapse patients	0	7	3
Relapse rate	0%	64% (7/11)	15% (3/20)

ΔX *Postoperative to follow-up*, Horizontal change from postoperative to follow-up; ΔX *preoperative to postoperative*, horizontal change from preoperative to postoperative; ΔY *postoperative to follow-up*, vertical change from postoperative to follow-up; ΔY *preoperative to postoperative*, vertical change from preoperative to postoperative.

COMPLICATIONS OF ORTHOGNATHIC SURGERY

Although complications can occur during any of the dental, orthodontic, or surgical phases of treatment, complications specifically related to the surgical procedures are summarized in Box 27-1. The specific problematic issues related to cleft orthognathic surgery were discussed in the preceding section. The complications discussed in this section are applicable to all patients undergoing orthognathic surgery.

Airway

Airway management is critical because nasoendotracheal intubation is necessary to facilitate intraoperative maxillary-mandibular fixation. Nasal intubation can be difficult in patients with clefts requiring orthognathic surgery who have previously undergone pharyngeal flap surgery. Intubation can be accomplished with fiberoptic guidance or exchanged for a stent after oral intubation. Occasionally, when nasal intubation is not possible, the oral tube can be brought out retromolar at the time of maxillary-mandibular fixation, although this is less than ideal, and unplanned extubation can occur. During the LeFort I surgical procedure, the nasotracheal tube is particularly at risk of septal-vomerine disjunction and the osteotomy of the lateral nasal wall. The nasotracheal tube can be lacerated or severed either by the osteotome or by the reciprocating saw.⁹⁷⁻⁹⁹ An immediate air leak or loss of air exchange is evident when blood is within the endotracheal tube. It is preferable to perform the septal disjunction first with a guarded osteotome to facilitate placement of the reciprocating saw as the septum and nasotracheal deflects to the opposite side and minimizes the risk of injury to the tube. The maxillary osteotomy with a reciprocating saw should be directed from medial to lateral in the opposite direction of the nasotracheal tube. If

Box 27-1 Complications of Orthognathic Surgery

LeFort I Procedure

- Arteriovenous fistulas (carotid-cavernous sinus)
- Avascular necrosis
- Infraorbital nerve traction injury
- Injury to the internal maxillary artery and its branches
- Injury to Stensen's duct
- Malocclusion
- Maxillary sinusitis
- Nasal septal deviation and buckling
- Nasopalatine nerve transection (inevitable)
- Ophthalmic and lacrimal duct injury
- Unanticipated fractures (pterygoid plate, sphenoid bone, middle cranial fossa)

VPD Osseous Genioplasty

- Inferior mandibular border contour irregularity
- Gingival recession
- Mental nerve injury
- Ptosis of the mentalis

BSSO

- Avascular necrosis
- Bleeding (inferior alveolar artery, masseteric artery)
- Condylar resorption
- Inferior alveolar nerve injury
- Malocclusion
- Malpositioned proximal segment
- Unanticipated fractures

Common to All Procedures

- Devitalization of teeth
- Hardware issues
- Injury to teeth
- Malunion/nonunion
- Postoperative infection
- Relapse
- Unanticipated fractures

injury occurs, exchange of the nasotracheal tube is easier before the maxillary osteotomy is completed.¹⁰⁰ The vast majority of patients are extubated immediately after the surgical procedure.¹⁰¹ Internal fixation with titanium plates and screws and postoperative maxillary-mandibular fixation with dental elastics over wire fixation have reduced the likelihood of prolonged postoperative intubation.¹⁰²⁻¹⁰⁹ Intermaxillary fixation increases airway resistance, reducing peak air flow, and patients who have undergone a LeFort I procedure also will, of necessity, have nasal airway obstruction.^{104,105} For these reasons, many prefer no maxillary-mandibular fixation or only guiding elastics in the immediate recovery period.

Hemorrhage

The use of local anesthesia with a vasoconstrictor and controlled hypotensive anesthesia will significantly reduce generalized bleeding and the need for blood transfusion while greatly improving the view of the operative field.^{106,107} Significant hemorrhage is uncommon; when it occurs, it is more likely with maxillary osteotomies.^{102,108} With maxillary osteotomy, the vessels at risk include the greater palatine vessels, maxillary artery, and pterygoid plexus.^{81,109} Bleeding from the descending palatine vessels occurs when the posterior aspect of the lateral nasal wall osteotomy is made, and in most circumstances the bleeding spontaneously stops. When bleeding persists, it is easily controlled with vascular clips or bipolar electrocautery after the maxilla is downfractured.

Because the separation of the pterygopalatine plate with an osteotome is not directly visible, placement of the osteotome at the inferior aspect by palpation is critical to avoid injury to the vessels within the pterygopalatine fossa.¹¹⁰ The margin of safety is approximately 10 mm.⁹⁸ Hemorrhage, when it occurs, can be rapid and is usually controlled by densely packing the fossa with cottonoid. In the vast majority of patients, bleeding, although it may be significant, is easily controlled with localized measures. Direct ligation of the maxillary or carotid artery is necessary only in rare circumstances.¹¹¹ In general, bleeding persists until the maxilla is downfractured and will nearly always be significantly diminished by the time the maxilla is repositioned with internal fixation.

In contrast, the incidence of significant hemorrhage with mandibular osteotomies (BSSO or IVO) is extremely low.¹¹²⁻¹¹⁶ The vessels at risk include the inferior alveolar artery, maxillary artery, facial artery, retromandibular vein, and pterygoid venous plexus.¹¹⁴ With subperiosteal dissection and the use of a medial ramus retractor, the inferior border retractor and lateral splitting will avoid vascular injury in most cases. With loss of the subperiosteal dissection plane (supraperiosteal), especially when exposing the medial surface of the ramus, injury to the vessels occurs, making the medial ramus osteotomy difficult. The use of cottonoid to pack the medial ramus will usually stop the bleeding, and in rare instances the split may need to be completed before the bleeding from the posterior ramal border can be controlled.

Despite all precautions, uncommon vascular complications that may be life-threatening can occur. These include arteriovenous fistulas, false aneurysms, carotid cavernous fistulas, and carotid artery thrombosis.¹¹⁷⁻¹²⁰

Vascular Compromise

With degloving, osteotomy, and repositioning of the facial skeletal elements, there is a significant reduction in the blood supply. The vascular compromise affects not only the skeletal component but also the dentition and associated soft tissue components (pulp, periodontium, and gingiva). In the vast majority of cases, vascular compromise is transient and has no significant clinical impact on the outcome.^{121,122} The degree of vascular compromise depends on the placement of the incision, the extent of degloving of the soft tissue, and the degree of mobilization and movement

of the segment. Additional factors that compromise the vascularity may include previous surgery for cleft reconstruction and adjuvant radiation therapy for head and neck cancer.

The vascularity of the LeFort I downfractured segment is derived primarily from the soft palate and buccal soft tissue pedicle, because the greater palatine vessels are frequently divided during the osteotomy and mobilization.^{80,81,110-124} Although the reduction in the blood supply is transient, devitalization of the teeth, periodontal defects, and segmental bone loss have been described.^{125,126} Many of these problems have been attributed to incisions that compromise the vascularity, excessive stripping of the periosteum, compromised palatal mucosa (previous cleft palate surgery), interdental osteotomies with loss of the attached gingiva, and transverse expansion with excessive stripping of the palatal mucosa. When intraoperative cyanosis of the gingiva is noted and the vascularity does not return with reversal of the hypotension, the surgeon should consider returning the maxilla to its original position and reassessing the surgical approach. When this occurs, readvancement can be gradual with the use of distraction osteogenesis, either surgically controlled with implanted devices or orthopedic elastic traction forces.

As with maxillary surgery, avascular necrosis with mandibular surgery is uncommon.^{121,127} The blood supply to the mandible is derived from the inferior alveolar artery and primarily from the nutrient vessels by way of the muscular attachments of the masseter and pterygoid muscles.¹²⁸ With the sagittal split ramal osteotomy, extensive stripping of the masseter from the buccal cortex may compromise the blood supply to the distalmost region of the proximal segment where internal fixation hardware is placed. Avascular necrosis, although uncommon, can occur, with resulting loss of fixation and skeletal stability. The blood supply to the distal element is derived from the attachment of the pterygoid muscle to the lingual cortex. Division of the pterygomasseteric sling, which is needed to allow adequate mobilization, should be carried out through the osteotomy between the buccal and lingual cortices. Although wide periosteal stripping is inevitable to allow visualization for ramal osteotomies, the surgeon must exercise care to expose only what is necessary.

Neurologic Complications

With the exception of the nasopalatine and superior alveolar nerves that are inevitably transected with the LeFort I osteotomy, the sensory loss of the infraorbital nerve distribution is temporary; there is nearly complete recovery, because the nerve is well visualized, and the vast majority of the osteotomies are inferior to the foramen. The long-term incidence is approximately 1.5% to 2%, and it may occur as a result of extensive traction from soft tissue retraction or compression at the time of plate fixation.^{109,129,130} The greater palatine nerve is frequently transected with the posterior osteotomy but without apparent significant sensory disturbance to the patient. Sensory deficits of the teeth and palatal and buccal mucosa seem to gradually resolve over a 12- to 18-month period. Other rare neurologic deficits of the second, third, fourth, fifth, sixth, tenth, and twelfth nerves have also been reported.¹³¹⁻¹³⁴ These are likely to occur as a result of unfavorable fractures ascending into the cranial base.

In contrast, the sensory deficit is the major concern with mandibular osteotomies, because the nerve is not visible and the surgeon relies primarily on anatomic data that are not specific to individual patients.^{112,113,135} Of the mandibular procedures, the sagittal split osteotomy of the ramus has the greatest risk of sensory loss.^{116,136} The inferior alveolar nerve is at risk at virtually every point during the sagittal split osteotomy procedure. The nerve is at risk with exposure of the medial ramus, the horizontal osteotomy of the medial ramus, the vertical osteotomy of the buccal cortex and the osteotomy along the external oblique ridge, the splitting of the ramus between the proximal and distal segments, and with fixation. Despite all precautions, a significant

percentage of patients will have sensory loss with or without transection. Transection that is apparent at the time of surgery is reported to range from 1.3% to 18%.^{102,115,135,137} Even without transection, long-term sensory loss in the inferior alveolar nerve is reported to occur in 24% to 85% of cases.^{112,113,135,138-140} Correlation between the surgeon's intraoperative assessment of the nerve injury and postoperative neurosensory deficit is poor; thus reacting to a perceived nerve injury that does not include complete transection is in most circumstances not indicated.^{141,142}

Other neurologic deficits have been reported with the sagittal split procedure.¹⁴³ The lingual nerve may be affected by the osteotomy of the inferior border, especially when an inferior border saw is used. Seventh nerve palsy is uncommon but has been reported to occur in 0.4% to 1% of patients because of the nerve's close proximity to the posterior border of the ramus.^{112,113,144} Unlike the sagittal split osteotomy, the risk of nerve injury with IVO is theoretically lower, although long-term sensory deficits range from 2.3% to 14%.^{116,136,145} Again, this is attributed to the inability to directly view the foramen located medially and placement of the vertical osteotomy well posterior based on lateral landmarks. Despite the significant percentage of neurosensory loss, patients are rarely bothered, and few, if any, mention it unless the surgeon asks. However, there should be a frank discussion with the patient before surgery, and if the patient cannot accept the possibility of sensory loss as a tradeoff for the benefits of occlusion, mandibular surgery should not be offered.

With osseous genioplasty, superficial distal fibers of the mental nerve are transected with the mucosal incision, and the mental nerve is at risk with the proximity of the osteotomy. Ideally, the osteotomy should be placed 4 to 5 cm below the foramen, because the nerve within the canal descends below before exiting the foramen. There may be insufficient bone below the foramen to safely carry out the osteotomy at this level, and the osteotomy is, of necessity, made proximal to the mandibular border, resulting in discontinuity when the symphysis is repositioned. At times, extending the mucosal incision or a second posterior exposure of the inferior border will facilitate visualization and the osteotomy. Despite precautions, the long-term sensory deficit has been reported to be as high as 20%.^{139,146,147} When osseous genioplasty is combined with a BSSO, as is frequently done, the long-term sensory deficit significantly increases from approximately 10% with genioplasty and 30% with a sagittal split osteotomy alone to 70% when a combined procedure is performed.^{126,133}

Infection

Postoperative surgical infection is uncommon after orthognathic surgery; the incidence is less than 1%.^{102,112,148-150} As with most operative procedures, the risk of infection increases with the length and type of the operative procedure. Bacterial contamination is inevitable, and the use of perioperative prophylactic antibiotics is common.^{148,151,152}

Unfavorable Osteotomies

With the LeFort I procedure, uncontrolled fractures extending into the cranial base occur when the osteotomies are incomplete and downfracture is attempted or when the pterygopalatine disjunction is improperly positioned, resulting in uncommon vascular, neurologic, and ophthalmic complications.¹⁵³⁻¹⁵⁵ The downfracture should occur with digital pressure alone, and Rowe disimpaction forceps should be used only for mobilization after the maxilla is separated from its base. Frequently, with digital pressure, sites of resistance can be identified, and these tend to occur at the posterior aspect of the lateral nasal wall and the posterior maxillary wall where the reciprocating saw was not fully positioned at its maximal depth. A thin osteotome can be introduced through the osteotomy of the anterior wall until resistance is felt. The osteotome should

be directed inferiorly from the orbital floor and posterior wall perforated with downward digital pressure until the maxilla downfractures. Whereas in developmental dentofacial deformities the maxilla readily downfractures because the posterior maxillary wall is thin and readily fractures favorably, in cleft and craniofacial cases the posterior wall is excessively thick, and an osteotome may be needed to fully complete the osteotomy. Although the traditional LeFort I osteotomy readily downfractures, the downfracture of the higher level LeFort I osteotomies that include the body of the zygoma does not readily occur and requires the surgeon to direct the osteotomy of the posterior lateral maxillary wall from the pterygoid plate superiorly with an osteotome. Visualization is difficult and requires an understanding of the 3D skeletal anatomy.

Unfavorable fractures from sagittal split osteotomies of the ramus occur with an incidence of 3% to 23%.^{102,113,115,137} These include condylar neck fractures, lingual plate fractures, and buccal plate fractures. The ideal split may be technically difficult to achieve, depending on the anatomic variations and ramal width and with it the ability to place and direct the osteotomes.¹¹³ Condylar neck fractures occur when the horizontal osteotomy is misdirected posterosuperiorly instead of horizontal to the occlusal plane. Buccal plate fractures typically occur when the vertical osteotomy at the inferior border is incomplete and a sagittal split with the osteotome is attempted. Lingual plate fracture may occur, typically originating near the ascending ramus and when the mandibular third molars have not been previously extracted. Unerupted third molars should be extracted 6 to 12 months before surgery to avoid uncontrolled fractures and allow ease of internal fixation.¹⁵⁶ Depending on the fracture pattern and whether there is advancement or setback, the surgery may proceed but will require principles of fracture management and prolonged postoperative maxillary-mandibular fixation.¹⁰² Alternatively, the procedure may need to be abandoned and the fractures allowed to heal before returning to the operating room.

Postoperative Malocclusion

Surgical malocclusion is uncommon but can occur and becomes readily evident in the early postoperative period.^{102,156-158} An early tendency to relapse can frequently be managed with class III or class II dental elastics and/or orthopedic appliances if minimal (edge-to-edge incisal relation). However, more significant recurrences of the initial preoperative occlusion in most circumstances necessitate a return to the operating room. In most cases, early failure results from inadequate mobilization of the repositioned jaws, bony interferences, and instability that is not detected during repositioning, condyles not passively seated within the glenoid fossa at the time of fixation, and issues related to internal plate-screw fixation. In addition, occlusal relapse can occur long after the initial surgery and is a result of complex functional dental and muscular forces reestablishing equilibrium and remodeling of the facial skeleton. Long-term follow-up is important, and management must be directed at the cause.

OUTCOMES

Unlike many surgical procedures, the outcome depends not only on the surgical procedure itself but also on a multitude of factors that exist long before the surgery, as well as on the ability to control variables long after the surgical procedure. Whether the desired long-term outcome is achieved in terms of occlusal function and aesthetics of the facial form depends on whether the goals of each of the phases of treatment were achieved. Moreover, the success of each phase depends on the preceding phase of treatment. For example, inadequate incisor decompensation limits the amount of sagittal repositioning possible and compromises the final facial aesthetics.

Fig. 27-65 A hierarchy of skeletal stability based on the vector of repositioning the maxilla and mandible.

If mobilization of the maxilla at the time of surgery is inadequate with a less than ideal occlusal relation obtained, the postsurgical orthodontic phase is prolonged and relapse toward the original condition is likely to occur.

With any skeletal movement, the surgeon must always be aware of the potential for relapse, even under an ideal setup and with the use of rigid internal fixation. As a general rule, the most stable moves are superior maxillary impactions, followed by mandibular advancement^{159,160} (see Fig. 27-63). In contrast, maxillary vertical lengthening, followed by mandibular setback, are less predictably stable procedures. The least stable is transverse maxillary widening. The stability of the repositioned maxilla and mandible is the subject of numerous publications¹⁶¹⁻¹⁶⁶ (Fig. 27-65). Many factors come into play, such as the specifics of the internal fixation, use of bone grafts, the period of postoperative occlusal stabilization, and amount of repositioning. Soft tissue forces directed against the vector of the surgical movement are significant. Ultimately, long-term skeletal stability requires neuromuscular adaptation.^{159,167,168} With maxillary impaction, the forces from the mandibular elevator muscles are favorable for maintaining the vector of movement, in contrast to maxillary vertical lengthening. Similarly, compensatory repositioning of the tongue to maintain the airway is more favorable with advancement than with setback.¹⁶⁹ Although it may seem reasonable that morphologic stability and physiologic adaptation should be complete 1 year after surgery, skeletal and dental changes can continue to occur.^{160,170,171}

CONCLUSION

Although orthognathic surgery involves restoring the skeletal anatomy, it is ultimately how the soft tissue drapes on the new facial skeleton that is the patient's concern.¹⁷² The surgeon must be well aware of the soft tissue response to the skeletal movements.¹⁷³ The goal is not necessarily to normalize the cephalometric values; the goal is to have the patient appear "normal" and to function "normally." The ability to predict the skeletal and soft tissue changes with orthognathic surgery is critical to treatment planning. With the current surgical techniques that use plate fixation,

the skeletal components can be repositioned with a relative degree of confidence. However, the soft tissue response is less predictable because of the multitude of uncontrolled variables, which include the surgical technique itself, the vectors and extent of repositioning, thickness of the musculature and subcutaneous adipose tissue, and ability of the soft tissue to adapt or conform to the new dentoskeletal morphology.^{163,174-181} Much of our knowledge about the soft tissue response is based on 2D cephalometric and photographic analysis. However, it is the 3D redraping of the soft tissue envelope to the new dentofacial skeletal morphology that requires quantification.¹⁸²⁻¹⁸⁴ Until sufficient data are available and better algorithms can be generated, orthognathic surgery remains an art based on the level of experience of the orthodontist and surgeon.

KEY POINTS

- Orthognathic or maxillofacial surgery should be thought of as a subcategory of craniofacial surgery.
- Indications for orthognathic surgery include facial dysmorphism with or without functional implications.
- Maxillofacial deformities can be broadly divided into three major categories: skeletal dysplasias, dental dysplasias, and dentofacial skeletal dysplasias.
- Correction of maxillofacial deformities requires careful analysis of the soft tissue with clinical examination and supporting photographs, skeletal evaluation with standardized radiographs, and dental evaluation with study models.
- In orthodontic-surgical management, the primary decision that must be made is whether the deformity is significant enough to require surgical repositioning, or whether orthodontic alignment of the dentition alone can be achieved without significantly compromising the facial aesthetics.
- The elements of the facial skeleton can be repositioned, redefining the face through a variety of well-established osteotomies.
- Various osteotomies are used to correct midfacial deformities; the choice of a particular procedure depends on the specific deformity.
- Orthognathic surgery to correct dentofacial deformities in patients with facial clefts is a more complex undertaking, because such patients present with not only skeletal considerations but also the soft tissue component, which plays a significant role in the management and outcome.
- Although orthognathic surgery involves restoring the skeletal anatomy, it is ultimately how the soft tissue drapes on the new facial skeleton that is the patient's concern. The surgeon must be well aware of the soft tissue response to the skeletal movements.

REFERENCES—With Key References Annotated

1. Wolfe SA, Berkowitz S. Plastic Surgery of the Facial Skeleton. Boston: Little Brown, 1989.
This excellent text from experienced craftsmen has much to teach the experienced plastic surgeon, the oral and maxillofacial surgeon, the ophthalmologic surgeon, and the neurosurgeon. It provides a systematic framework for disassembling and then reassembling the craniofacial skeleton. The principles of skeletal surgery are elucidated in more than 250 cases based on personal experience by a single surgeon and orthodontist. With its phenomenal wealth of clinical cases and logical approach to reconstructing complex craniofacial skeletal deformities, this book is essential study for the practicing craniofacial surgeon.

4. Sarver DM. Esthetic Orthodontics and Orthognathic Surgery. St Louis: Mosby-Year Book, 1998.
The author stresses the contemporary aesthetic components of orthodontic-orthognathic surgical principles over surgical treatment planning based on cephalometric analysis alone. This text should be considered essential reading not only for oral and maxillofacial surgeons but also for plastic surgeons so they can understand the influence of the maxillary-mandibular skeletal position on soft tissue draping.

9. Ackerman JL, Ackerman MB, Brensinger CM, et al. A morphometric analysis of the posed smile. Clin Orthod Res 1:2, 1998.
10. Arnett GW, Bergman RT. Facial keys to orthodontic diagnosis and treatment planning. Part I. Am J Orthod Dentofacial Orthop 103:299, 1993.
This article, which is the first of two parts (see also reference 11), presents a systematic approach to clinical facial analysis; it discusses the soft tissue changes associated with orthodontic and surgical treatments of malocclusion and the impact of dental movement, whether orthodontic or surgical, to achieve aesthetic goals. Although primarily geared toward orthodontists involved in surgical cases, the article is equally essential for surgeons so they can have a common understanding of goals.
11. Arnett GW, Bergman RT. Facial keys to orthodontic diagnosis and treatment planning. Part II. Am J Orthod Dentofacial Orthop 103:395, 1993.
12. Sarver DM, Ackerman JL. Orthodontics about face: the re-emergence of the esthetic paradigm. Am J Orthod Dentofacial Orthop 117:575, 2000.
The traditional approach to diagnosis and treatment planning has been based on hard tissue relationships and the Angle classification, which considers ideal dental occlusion "nature's intended ideal form." These authors describe how the ideal occlusion is the exception rather than the rule and state that the orthodontist's and surgeon's task is to achieve the occlusal and facial outcomes that will most benefit each patient, whose aesthetic concerns are often paramount. The article refocuses orthodontic treatment planning using soft tissue assessment in the context of each patient's dentoskeletal deformity.
13. Sarver DM, Ackerman MB. Dynamic smile visualization and quantification. Part 1. Evolution of the concept and dynamic records for smile capture. Am J Orthod Dentofacial Orthop 124:4, 2003.
14. Sarver DM. The importance of incisor positioning in the esthetic smile: the smile arc. Am J Orthod Dentofacial Orthop 120:98, 2001.
Traditional assessment of the upper lip-dental relationship has been based on static measurements. This key article focuses on the dynamic nature of the smile. The author defines the smile arc as the relationship of the curvature of the incisal edges of the maxillary incisors and canines to the curvature of the lower lip in the posed smile. The ideal smile arc has the maxillary incisal edge curvature parallel to the curvature of the lower lip. This article presents the concept of the smile arc and how it relates to orthodontics to optimize the appearance of the smile.

17. Büttow KW. A lateral photometric analysis for aesthetic-orthognathic treatment. *J Maxillofac Surg* 12:201, 1984.
18. Obwegeser HL, Marentette LJ. Profile planning based on alterations in the positions of the bases of the facial thirds. *J Oral Maxillofac Surg* 44:302, 1986.
This classic article shows how to properly analyze the profile using the size and position of the bases of the facial thirds. Using the average face as a reference, the bases of the facial thirds are repositioned along a horizontal or vertical direction, and the soft tissue profile is redrawn to correspond to the skeletal changes. This article illustrates how the underlying skeletal abnormalities influence the profile and determine the various facial morphologies encountered by the surgeon.

27. Fish LC, Epker BN. Surgical-orthodontic cephalometric prediction tracing. *J Clin Orthod* 14:36, 1980.
28. Zide B, Grayson B, McCarthy JG. Cephalometric analysis for upper and lower midface surgery. Part II. *Plast Reconstr Surg* 68:961, 1981.
In a series of excellent articles (see also reference 29), Zide et al present a practical approach to cephalometric analysis that allows surgical residents to understand its role in evaluating the skeletal deformity. The approach is systematic and well illustrated by clinical examples. Surgical residents who carefully work through the examples will have learned a language that will allow them to communicate with their orthodontic colleagues.
29. Zide B, Grayson B, McCarthy JG. Cephalometric analysis for mandibular surgery. Part III. *Plast Reconstr Surg* 69:155, 1982.
30. Rosen H. When osteotomies should be considered. *Clin Plast Surg* 18:205, 1991.
Many patients seeking cosmetic surgery are under the impression that their deformity requires soft tissue redraping. This article should be read by all plastic surgery residents, because it discusses the skeletal components of facial disharmony of which they must be cognizant when evaluating and possibly addressing patients who seek cosmetic surgery to achieve the desired aesthetic outcome.

71. Stokbro K, Aagaard E, Torkov P, et al. Virtual planning in orthognathic surgery. *Int J Oral Maxillofac Surg* 43:957, 2014.
72. Schendel SA, Carlotti AE Jr. Nasal considerations in orthognathic surgery. *Am J Orthod Dentofacial Orthop* 100:197, 1991.
73. Freihofer HP. Latitude and limitations of midface movements. *Br J Oral Maxillofac Surg* 22:393, 1984.
74. Kawamoto HJ Jr. Simplification of the Le Fort I osteotomy. *Clin Plast Surg* 16:777, 1989.
Few articles have so elegantly demystified the LeFort I procedure as this brief article. It is essential reading for surgical residents.
75. Bell WH, ed. *Modern Practice in Orthognathic and Reconstructive Surgery*. Philadelphia: WB Saunders, 1992.
Both this edition and the classic 1980 edition are comprehensive three-volume texts that provide the fundamentals of integrated surgical-orthodontic treatment of patients with dentofacial skeletal deformities. A thorough study of both editions is essential for practicing maxillofacial surgeons whose surgical education is rooted in plastic surgery or oral surgery.
76. Posnick JC. LeFort I osteotomy, sagittal splitting of the mandible and genioplasty: historical perspective and step-by-step approach. In Posnick JC, ed. *Craniofacial and Maxillofacial Surgery in Children and Young Adults*, vol 2. Philadelphia: WB Saunders, 2000.
The section on orthognathic surgery is illustrated with a wealth of case studies that demonstrate patient evaluation, management, and outcomes. This particular chapter on the surgical technique will provide surgical residents with excellent views of the procedures that are the cornerstones of orthognathic surgery.
77. Obwegeser HL. *Mandibular Growth Anomalies*. Berlin: Springer, 2001.
Perhaps no other individual has formally developed the specialty of orthognathic surgery as has Hugo Obwegeser. Thus this text is an invaluable reference to surgeons and orthodontists alike to understand the historical development of orthognathic surgery and to provide a unique insight into the thought processes of a creative surgeon.
78. Patel PK, Novia MV. The surgical tools: the LeFort I, bilateral sagittal split osteotomy of the mandible, and the osseous genioplasty. *Clin Plast Surg* 34:447, 2007.
79. Siebert JW, Angrigiani C, McCarthy JG, et al. Blood supply of the Le Fort I maxillary segment: an anatomic study. *Plast Reconstr Surg* 100:843, 1997.
80. Bell WH, Fonseca RJ, Kennedy JW, et al. Bone healing and revascularization after total maxillary osteotomy. *J Oral Surg* 33:253, 1975.
This classic article using rhesus monkeys demonstrated that transection of the greater palatine arteries had no discernible effect on the circulation to the teeth and bone in the maxilla and its enveloping soft tissues. The palatal mucosa and labial-buccal gingiva provide an adequate nutrient pedicle for single-stage total maxillary osteotomies.
81. Epker BN. Vascular considerations in orthognathic surgery. II. Maxillary osteotomies. *Oral Surg Oral Med Oral Pathol* 57:473, 1984.
82. Smith BR, Rajchel JL, Waite DE, et al. Mandibular anatomy as it relates to rigid fixation of the sagittal ramus split osteotomy. *J Oral Maxillofac Surg* 49:222; discussion 227, 1991.
83. Ritter EF, Moelleken BR, Mathes SJ, et al. The course of the inferior alveolar neurovascular canal in relation to the sliding genioplasty. *J Craniofac Surg* 3:20, 1992.
This classic article describes the course of the inferior alveolar nerve relevant to the osseous genioplasty. There is a significant variability, and the authors recommend that the symphyseal osteotomy be 6 mm inferior to the mental foramen to reduce nerve injury.
84. Keller EE, Sather HA. Quadrangular Le Fort I osteotomy: surgical technique and review of 54 patients. *J Oral Maxillofac Surg* 48:2; discussion 12, 1990.

86. Janulewicz J, Costello BJ, Buckley MJ, et al. The effects of Le Fort I osteotomies on velopharyngeal and speech functions in cleft patients. *J Oral Maxillofac Surg* 62:308, 2004.
This article details a retrospective study from the University of Pittsburgh on the effects of orthognathic surgery on velopharyngeal and speech functions. The study objectively and subjectively evaluates the quality of speech in 54 patients who underwent orthognathic surgery between 1981 and 2004.
87. Watzke I, Turvey TA, Warren DW, et al. Alterations in velopharyngeal function after maxillary advancement in cleft palate patients. *J Oral Maxillofac Surg* 48:685, 1990.

88. Phillips JH, Klaiman P, Delorey R, et al. Predictors of velopharyngeal insufficiency in cleft palate orthognathic surgery. *Plast Reconstr Surg* 115:681, 2005.
This article is a retrospective study from the Hospital for Sick Children and others in Canada that includes 26 patients who underwent orthognathic advancement. Assessments of speech and velopharyngeal function before and after orthognathic surgery and the role of nasopharyngoscopy are detailed.
89. Witzel MA, Munro IR. Velopharyngeal insufficiency after maxillary advancement. *Cleft Palate J* 14:176, 1977.
90. Dalston RM, Vig PS. Effects of orthognathic surgery on speech: a prospective study. *Am J Orthod* 86:291, 1984.
91. Posnick JC. Cleft-orthognathic surgery: the unilateral cleft lip and palate deformity. In *Craniofacial and Maxillofacial Surgery in Children and Young Adults*. Philadelphia: WB Saunders, 2000.
In this comprehensive chapter, the author provides a detailed description of his surgical technique in the unilateral cleft patient, including his preoperative evaluation and results for 35 patients who underwent LeFort I maxillary osteotomy.
92. Heliövaara A, Ranta R, Hukki J, et al. Skeletal stability of Le Fort I osteotomy in patients with isolated cleft palate and bilateral cleft lip and palate. *Int J Oral Maxillofac Surg* 31:358, 2002.
This article from Helsinki, Finland, retrospectively evaluates the skeletal stability and relapse rate of 25 patients who underwent correction of maxillary hypoplasia via orthognathic surgery. Fourteen patients had isolated cleft palate (mean age 27.2 years), and 11 patients had bilateral cleft lip and palate (mean age 23.7 years). The authors evaluate surgical advancement and relapse in both the horizontal and vertical dimensions.
93. Hirano A, Suzuki H. Factors related to relapse after Le Fort I maxillary advancement osteotomy in patients with cleft lip and palate. *Cleft Palate Craniofac J* 38:1, 2001.
This article from Nagasaki University School of Medicine in Japan is a retrospective study of 58 patients (42 unilateral cleft lip/palate and 16 bilateral cleft lip/palate) who underwent orthognathic surgery to correct maxillary hypoplasia. The authors report a mean follow-up period of 2½ years. Based on cephalometric and statistical analyses, the authors elucidate factors related to relapse after BSSO.
94. Cho BC, Kyung HM. Distraction osteogenesis of the hypoplastic midface using a rigid external distraction system: the results of a one- to six-year follow-up. *Plast Reconstr Surg* 118:1201, 2006.
This article reports the authors' experience at Kyungpook National University in Korea using external distraction to correct severe maxillary hypoplasia. They present results of nine patients and include the advantages and disadvantages of their procedure.
95. Polley JW, Figueroa AA. Rigid external distraction: its application in cleft maxillary deformities. *Plast Reconstr Surg* 102:1360; discussion 1373, 1998.
96. Kumar A, Gabbay JS, Nikjoo R, et al. Improved outcomes in cleft patients with severe maxillary deficiency after Le Fort I internal distraction. *Plast Reconstr Surg* 117:1499, 2006.
This article reports the authors' experience at the University of California, Los Angeles, with the use of internal distraction to correct severe maxillary hypoplasia. They present a comparative analysis of 51 patients who underwent correction of maxillary deficiency by LeFort I osteotomy and advancement by a conventional orthognathic procedure and internal distraction.

Alveolar Cleft Surgery

Denver M. Lough • Christopher L. Madsen
Anand R. Kumar • Alexander Y. Lin

Power Iliac Crest Bone Graft Harvest; Imaging, Surgical Markings for Power Iliac Crest Bone Graft Harvesting, and Placement of Bone Graft in the Alveolar Cleft.

The study and treatment of the alveolar cleft have remained a less characterized and often underappreciated component of cleft care in the plastic surgery literature. The alveolus is the functional keystone in the management of the complete cleft lip phenotype because of its position at the apex of the primary palate and junction with the secondary palate. The ultimate repair of the persistent alveolar bone defect after initial cleft lip and palate surgery is of great importance in properly creating a unified maxilla and solid foundation for future facial skeletal surgery.

The goals of successful bone reconstruction include:

- Optimal dental eruption and salvage of permanent teeth erupting within the cleft
- Creation of a stable one-piece dental and maxillary arch
- Proper skeletal support for the nose
- A durable substance between oral and nasal lining repairs, decreasing the chance for recurrent oronasal fistula
- Creation of adequate bone stock for future dental restoration with osseointegrated implants or orthodontic canine substitution

This chapter will focus on the comprehensive management of the alveolar cleft defect from infancy (deciduous dentition) through mixed dentition and finally with permanent dentition while highlighting the advances in bone biology that have improved on results during the first decade of the twenty-first century.

German surgeons Lexar, Drachter, and von Eiselbergin¹ first reported the repair of alveolar and maxillary defects with bone grafts in cleft patients in the early 1900s. Although described nearly 100 years ago, reconstruction of the maxillary and alveolar defects in cleft patients was rarely practiced until Boyne and Sands² reported their experience in 1972 with secondary autograft bone grafting of palate and alveolar defects in 12 cleft patients in mixed dentition. Currently, autograft iliac crest bone remains the most commonly used graft material. Yet, significant donor-site morbidity, including meralgia paresthetica, hematoma, intestinal herniation, infection, and postoperative fractures, persists with this approach.^{3,4}

Significant controversy remains regarding the optimal management of the cleft alveolus, including optimal timing of surgery (infancy, mixed dentition, or permanent dentition), the type and location of osseous grafting material, and the optimal design and transposition of vascularized tissue to promote graft material healing and minimize future dental complications, such as gingival recession. The plethora of treatment options and the paucity of comparative outcome data arguably define the cleft alveolus as the least studied and most enigmatic aspect of comprehensive cleft care.⁵⁻¹⁶ This chapter will explore each of these critical controversies and provide reasonable treatment recommendations for the treatment of the cleft alveolus.

EPIDEMIOLOGY AND EMBRYOLOGY

The incidence of the cleft alveolus mirrors that of the common cleft lip and varies greatly based on race and ethnicity. In white populations, the incidence has been reported as high as 1 per 1000 live births and as low as 0.41 per 1000 live births in populations of African descent.¹⁷ Asian populations, including the Indian subcontinent, have rates twice as great (2 per 1000 live births).¹⁷ Interestingly, the incidence of clefting isolated to the secondary palate has been reported at 0.5 per 1000 live births and similar among various ethnic and racial groups.¹⁸⁻²⁰

Most children born with a cleft lip, including the primary palate, are males, whereas isolated clefts of the secondary palate typically occur more commonly in females.²⁰ The incidence of unilateral cleft lip occurs twice as often on the left side compared with the right side. Unilateral cleft lip and primary palate occurs more frequently than bilateral cleft lip at a ratio of 9:1.²⁰ A notable phenomenon is isolated bilateral clefts of the lip only that more commonly present with an associated cleft of the secondary palate in 86% of bilateral cleft cases. In contrast, a unilateral cleft lip is diagnosed with a concurrent cleft of the secondary palate in 68% of cases.²⁰

The pathogenesis of facial cleft has generally been thought to result from a failure of fusion of any of the five developing facial elements that include the frontonasal process, the two lateral maxillary processes, and the two mandibular processes of the embryo. By the fourth week of gestation, neural crest cells from the ectoderm proliferate and migrate to form a substantial portion of the facial mesenchyme. By the end of the fifth week, the maxillary prominences have enlarged and merged with the lateral nasal prominences, establishing continuity between the nose and cheek and have fused with the medial nasal prominences, establishing continuity of the lip. Failure of any one or both of the maxillary prominences to merge with the fused medial nasal prominences results in a unilateral or bilateral cleft of the lip, respectively. Plate formation begins during the fifth week of gestation and is completed by the twelfth week of gestation. Failure of fusion of the median palatine process that is derived from fusion of the median nasal processes results in creation of the primary cleft palate or cleft alveolus. The primary palate, when properly formed, will become the premaxillary segment of the upper jaw. This segment ultimately gives rise to the alveolar structures, including the dentition and portion of the hard palate anterior to the incisive foramen.²⁰

Fig. 28-1 A cleft alveolus demonstrating its shape, resembling a platonic solid or tetrahedron. The apex of the shape corresponds to the incisive foramen. The cleft represents a discontinuity of the maxilla into two pieces in the unilateral cleft lip. As suggested by the figure, routine cleft repair without gingivoperiosteoplasty does not address the bone defect.

NORMAL AND ABNORMAL ANATOMY

The *alveolar cleft* is a complex defect that has a shape resembling a regular convex polyhedron or platonic solid, such as the tetrahedron when fully developed before reconstruction with bone graft, and is a critical component of the complete cleft lip deformity (Fig. 28-1). In an isolated cleft of the secondary palate, the maxillary alveolus is complete and intact. In the *unilateral complete cleft lip*, the maxilla is separated into a major or greater segment, usually on the cleft side, and minor segment opposite. The vomer bone is usually fused to the major segment and exposed on the side of minor segment within the oronasal cleft defect. In *bilateral clefts*, however, the vomer bone and associated mucosa are exposed on both sides and fused to the premaxilla, creating an unfavorable condition in which vomer-directed growth is unrestrained or guided by either lateral maxillary segment (fly away premaxilla). Whether unilateral or bilateral, the alveolar cleft is lined by both nasal and oral mucosa that ultimately becomes continuous with the buccal mucosa on the labial side, continuous with the palatal mucosa on the palatal side, and contains varying amounts of keratinized gingival epithelium at the anterior cemento-enamel junction.

TIMING OF SURGERY

Significant controversy exists regarding the optimal time for treatment of the alveolar cleft. A significant concern with most bone-related surgery is the requirement for subperiosteal exposure that may ultimately devascularize the adjacent bone and secondarily disrupt or inhibit future facial growth. When alveolar bone graft (ABG) cleft surgery is performed early, before any tooth development, it can be done with bone or cartilage graft (primary ABG) or without grafting material that is known as *gingivoperiosteoplasty* (GPP), which is performed at the time of the primary cleft lip repair. Whether repaired early or late, the cleft alveolus–maxillary bone defect is treated by the multidisciplinary cleft-craniofacial team; the orthodontist first aligns the maxillary segments over several months, followed by surgical alveolar bone grafting, where the bone graft is placed in the alveolar-maxillary gap, covered by vascularized soft tissue, to unite the maxillary segments into one stable alveolar-maxillary complex. When the bone graft survives in this new

Table 28-1 Treatment Options From Infancy to Adolescence

Infancy: Primary Dentition	Childhood: Mixed Dentition	Adolescence: Permanent Dentition
Dentoalveolar molding, primary grafting, gingivoperiosteoplasty	Orthodontics, secondary grafting	Orthodontics, orthognathic surgery, late repair

location, it can facilitate dental eruption and future orthodontic movement of teeth into the new bone to treat potential cleft dental gaps resulting from missing or malformed teeth within the cleft defect.²¹ The bone graft material is most commonly harvested from autologous iliac crest bone graft (ICBG), although anterior tibia rib and cranium are well-reported alternate harvest sites.²²⁻²⁵ ICBG is usually performed during the period of mixed dentition (secondary ABG) between 7 to 12 years of age, whereas primary GPP repair of the cleft lip-alveolus is typically performed between 3 and 6 months of age. Table 28-1 shows current treatment options for the cleft alveolus based on age of the child, and the concurrent dental development highlights primary versus secondary grafting versus late grafting.

Maxillary Growth

Multiple studies have suggested that surgery attenuates maxillary growth. Lateral cephalometric analyses in the 1950s through the 1970s showed that nonoperated clefts and noncleft controls had no differences in sagittal facial growth other than the region of the cleft.²⁶⁻²⁹ These studies demonstrated that children with clefts have the potential for normal facial growth, and that the surgery itself likely affects growth to some degree. Motohashi et al³⁰ demonstrated that unrepaired adult clefts have wider faces (other than their maxilla) than noncleft control subjects, but repaired adult clefts have narrower maxillas than noncleft control subjects. This finding occurred in patients who only were treated with primary lip and palate repairs without specific treatment of the cleft alveolus. This documented concern of negatively impacting maxillary growth with bone grafting is a common reason for the generally accepted delayed treatment of the cleft alveolus until the mixed dentition period, which typically occurs between 7 and 12 years of age.³¹⁻³⁶ When reconstruction is performed during mixed dentition, it is commonly reported as *secondary ABG*.

When alveolar bone grafting is performed before or during deciduous dentition or before the age of 6 years, this is commonly referred to as *primary ABG*. Many authors have reported decreases in maxillary growth with primary ABG.³⁷⁻⁴⁰ However, in a six European center comparison, Molsted et al⁴¹ showed that primary ABG may have the advantage of more symmetrical dentoalveolar development when viewed from the frontal plane. These findings are intuitive, because early repair of the alveolar cleft may cause less tipping of the teeth and the actual maxillary segments on either side of the alveolar cleft. In the same study, the primary ABG group demonstrated improved symmetry but also decreased maxillary growth in the sagittal and transverse planes.⁴¹ Trotman et al⁴² similarly showed improved dental inclination with primary alveolar bone grafting. Both teams used presurgical orthopedics (appliances to align the infant alveolus). There is concern that presurgical orthopedics may negatively affect maxillary growth.

Enemark et al⁴³ followed 224 cleft patients for 4 years. They were separated into three groups: (1) those who received an ABG before canine eruption (mean age 10 years), (2) those who received an ABG after canine eruption (mean age 13.1 years), and (3) those whose ABG was delayed (after 16 years of age). All patients were compared with a control group of patients with nongrafted

unilateral clefts. All their patients had transverse expansion of the maxilla orthodontically before bone grafting. Enemark's team demonstrated that sagittal maxillary growth was not affected by secondary bone grafting when compared with a nongrafted cleft control subject, but that *anterior facial height* (nasion to anterior nasal spine, or N-ANS) showed less growth in patients with a grafted cleft. Maxillary length was shorter in the after canine eruption group compared with the precanine eruption group; both were shorter than that in the control group. Overall, the youngest group (precanine eruption) had the best levels of alveolar bone at the gingival margin.

Collectively, studies related to the maxillary arch suggest that earlier ABG is better for the height of the alveolar bone and symmetry of the frontal plane, but probably negatively affects some aspect of maxillary growth (for example, height and anteroposterior length).³⁶⁻⁴² The studies cited had mixed results with respect to maxillary width (transverse growth), possibly because of variance in the use of maxillary expansion. Maxillary expansion before ABG may have compensated for any detrimental effects of the bone grafting procedure itself on maxillary transverse growth. Many teams prefer to avoid early bone graft and prefer grafting in mixed dentition before the eruption of the canine teeth, because this group had the best outcomes in the study by Enemark et al.⁴³ Despite this, approximately 25% of children with unilateral cleft lip and palate will require LeFort I maxillary advancement surgery at skeletal maturity to gain a normal bite and appearance.⁴⁴

Dentition and Orthodontia

A detailed review of the literature demonstrates that successfully spontaneous eruption of the canine tooth through ABG material varies from 27% to 97% and averages approximately 75%.³⁶ For teeth on either side of the cleft, both primary ABG and secondary ABG showed improved dental inclination.^{41,42} Less known is whether dentition can be damaged by ABG. Early surgery in the cleft area seems to disturb the development of the permanent lateral incisor.⁴⁵ However, Enemark et al.⁴³ found greater risk of loss of teeth from external root resorption only in their two older groups, possibly from an ABG damaging the periodontal ligament or cementum of the root surfaces. The fate of the cleft tooth in the setting of an ABG is not always clear from these studies; Enemark et al.⁴³ rated the functional and aesthetic properties of the reconstructed alveolus to be better in their youngest group (average 10 years) compared with their older groups (average 13.1 years and older than 16 years) for both unilateral and bilateral clefts.

Gingivoperiosteoplasty

GPP is based on the principle of guided tissue regeneration—that subperiosteal exposure of the alveolar edges will allow growth of bone without the need for bone grafting. This is typically performed during one of the infant cleft surgeries, most commonly with the primary cleft lip repair.

In the original Skoog technique, presurgical apposition was not used and was reported to minimally affect facial growth.^{46,47} Other researchers have contested these findings on secondary analysis.⁴⁸ The use of an active presurgical Latham appliance, followed by GPP, was associated with poor maxillary growth.⁴⁹ Passive molding followed by GPP has been reported to not significantly affect facial growth, although only 80% had bone formation, and of those, 40% required secondary bone grafting.⁵⁰ Indications for GPP are well-approximated alveolar clefts, with a limited gap between segments of 1 to 2 mm, and therefore require presurgical infant orthopedics (nasalveolar molding, taping, and lip adhesion), to facilitate alveolar segment alignment before GPP.⁵⁰ Given the distinct timing of primary and secondary grafting, the surgical techniques described in the next section will be discussed separately for either GPP or ABG.

PREOPERATIVE ASSESSMENT

Patient History and Physical Examination

For both GPP and ABG, it is critical that the alveolar segments are well approximated before surgery. In an infant, this may be done with nasoalveolar molding, taping, lip adhesion, or other presurgical orthopedics to approximate the alveolar segments. GPP can be done at the time of cleft lip repair or cleft palate repair, although it is typically done during cleft lip repair.

In ABG, palatal expansion is usually performed before the ABG to align the segments into a smooth, curved arch form. There is controversy regarding timing of palatal expansion before or after ABG or both. Teeth within the cleft alveolar margin may inhibit optimal watertight closure of the vascularized flap and may require extraction 2 months before ABG to allow healing and facilitate subsequent vascularized flap closure of the cleft defect.

An unusually wide alveolar cleft may be treated by first collapsing the defect to create a smaller cleft defect to facilitate closure, followed by expansion 1 to 2 months after repair. Another option is staged soft tissue closure with vascularized flaps, followed by bone grafting 3 months later.

Evaluation

Evaluation begins based on the treatment philosophy of the cleft-craniofacial team. When will the procedure to correct the alveolar defect take place?

- In the neonatal period (primary repair), reconstructed at the time of the cleft lip repair with the use of GPP
- In the mixed dentition period (secondary repair), before the eruption of the canine tooth
- In the permanent dentition period (tertiary repair), after the eruption (or impaction) of the canine tooth

Patients in the last category have often had prior failed treatment either during primary or secondary repair. Team evaluation by the surgeon, pediatric dentist, and the craniofacial orthodontist is necessary to coordinate optimal treatment. The critical factors in developing the treatment plan before alveolar repair are based on the timing of the repair (Box 28-1).

We prefer secondary alveolar bone reconstruction (ABR) during mixed dentition. The evaluation process typically begins by 8 to 9 years of age to minimize patient anxiety typically present when orthodontic treatments are started before the age of 8 years. In addition, eruption of

Box 28-1 Primary, Secondary, and Tertiary Repair Plans

- Primary repair: Alignment of the maxillary-alveolar segments and narrowing the intersegment gap to under 1 to 2 mm to facilitate tension-free repair
- Secondary repair: Alignment of the maxillary-alveolar segments and narrowing of the intersegment gap to under 8 mm and early decisions regarding extraction of unusable teeth or canine substitution into the lateral position in patients missing a lateral incisor
- Tertiary repair: Alignment of the maxillary-alveolar segments and narrowing of the intersegment gap to under 8 mm and definitive decisions regarding extraction of unusable or carious teeth and canine substitution

the permanent central incisors and permanent first molar (6-year molar, because it arises around 6 to 7 years of age) is necessary to use tooth-borne palatal expansion. We follow cleft tooth (lateral incisor or canine) development, but begin expansion when the child can tolerate expansion rather than wait for traditional development of two thirds of the canine root. Our experience suggests that waiting to initiate orthodontic treatment leads to delays in alveolar cleft reconstruction because of the significant time requirements needed for controlled arch expansion. In rare instances bone-borne palatal expansion devices may be necessary because of the inability to maintain expansion with tooth-borne systems or to bond a device to the permanent teeth as a result of delayed or inadequate molar eruption. Finally, in patients with large bilateral alveolar cleft defects, a staged approach reconstructing only one side at a time and separating the second stage by 3 to 4 months has proved a useful treatment strategy in the high-risk case.

Imaging

Imaging with traditional dental radiographs, including the pantomogram and apical and occlusion techniques, has been used extensively for more than 40 years. Imaging scoring systems, including the Enemark and Chelsea scoring systems,⁴³ have used changes based on apical imaging views before and after intervention (Fig. 28-2). Within the past decade, cone-beam computed tomography (CBCT) has emerged as the imaging modality of choice because of the superior imaging quality when compared with apical dental radiographs. In addition, CBCT data can be reformatted with software algorithms to provide a standard cephalogram and pantomogram and therefore theoretically reduce the total radiation dose to the patient without compromising imaging quality or completeness of the dentofacial imaging record. CBCT also provides data to help determine the root development of the cleft tooth (lateral incisor or canine) and measure the dimensions of the alveolar cleft, including volume loss and relative amount of bone graft necessary for complete reconstruction.

Fig. 28-2 **A**, An apical dental radiograph showing a typical unilateral alveolar cleft defect before treatment with adjacent deciduous and permanent teeth on either side of the cleft bone defect. **B**, An apical dental radiograph showing the same unilateral alveolar cleft region after treatment with our preferred technique of minimal access ICBG and allograft bone graft. Note the complete obliteration of the cleft bone defect and replacement with mature bone that has supported eruption of the adjacent teeth. This is a typical Enemark 1 result.

OPERATIVE TECHNIQUE

Principles of Alveolar Bone Grafting

There are multiple techniques for bone graft reconstruction (Box 28-2) and vascular coverage (Box 28-3).

Complete reconstruction of the alveolar cleft defect requires proper closure of the roof (nasal side), floor (palatal side), and anterior (labial side) gingiva and mucosa of the upper lip. It also requires elevation of a contiguous gingivoperiosteal flap to the first molar on the cleft side (or both in bilateral cases) and to the contralateral incisors on the noncleft side (or not crossing the prolabium to avoid devascularizing the premaxilla in bilateral cases). Alternatively, gingival and buccal flaps can be separately elevated, as reported by Precious.⁵¹

The mucosa overlying the alveolar cleft is divided to create nasal-palatal flaps. We recommend a marginal incision within the arch of the alveolar cleft, whereas others recommend that the incision be placed more labially to allow larger turnover flaps to line the limited nasal floor. We avoid using this technique, because it places nonrespiratory mucosa in the nasal cavity. Regardless, the exposure must be in the subperiosteal plane to fully expose the bone defect and remove any intervening soft tissue that may limit ultimate alveolar fusion. Depending on the size of the alveolar cleft, this exposure may just graft the leading edge of the alveolus, or more typically, needs to reopen and cross the scar tissue of the original oronasal fistula repair (that is, the original primary cleft lip repair) to ensure full takedown and closure of the residual oronasal fistula. This theoretically would only go posteriorly as far as the incisive foramen, because this is the limit of the alveolar cleft. However, in certain patients with unrepaired clefts or large preexisting oronasal fistulas, this dissection may have to proceed further posteriorly.

The nasal flaps need to be reapproximated tightly to avoid persistent oronasal fistula or communication of the nasal cavity with the underlying alveolar graft material. This is typically done with an absorbable suture but may be augmented by other materials, such as allograft dermis (for example, AlloDerm) or tissue sealant (for example, Tisseel). Methylene blue through the cleft nostril may be used to test for the presence of functional leakage through an oronasal fistula.

Box 28-2 Techniques for Bone Graft Reconstruction

- No bone graft: Avoid bone grafting the osteogenic reconstruction with GPP
- Autograft bone graft: Various donor-site locations, although the most common is the iliac crest
- Allograft bone graft: Corticocancellous chips, demineralized bone matrix, or a combination of both
- Biologic agents: Bone morphogenetic protein, platelet rich plasma

Box 28-3 Techniques for Vascular Coverage

- Sliding gingivoperiosteal flaps with or without lateral relaxing incisions
- Transposition local mucosal flaps
- Regional flaps (tongue or facial artery musculomucosal flaps)
- Palatal flaps
- Allograft skin substitutes

Fig. 28-3 Our preferred incision for elevation of gingivoperiosteal upper lip sulcus flaps. Note that medial transposition will ensure that gingival tissue will be placed into its correct position after closure. Placement of buccal tissue in the gingival position may close a fistula but will increase the risk of future tissue recession and ultimate exposure of the cemento-enamel junction.

Depending on the size of the flaps, palatal flaps may need to be elevated to ensure complete floor support of the bone graft. For the largest clefts or those with extensive oronasal fistula, staged repair of the palate floor may be necessary before definitive ABG.

After adequate exposure, full development of the alveolar cleft defect, and closure of the oral and nasal surfaces, the defect is filled with grafting material. An ICBG is typically harvested through an incision lateral and inferior to the anterior superior iliac spine to avoid injury to the lateral femoral cutaneous nerve. Variations include limiting the incision to a stab incision with a trephine (Acumed) to harvest columns of bone.^{7,52} Other authors have described the use of cadaveric bone allograft and bone morphogenetic protein 2 (BMP-2).^{7,53-58} Regardless of the technique, bone graft or bone substitute must be packed against the exposed alveolar bone edges to allow protected regeneration of bone for osteoconduction and likely osteoinduction in fresh bone graft, cadaveric bone allograft (for example, DBX Mix, Synthes), and BMP-2. Some practitioners will decorticate the alveolar edges until bleeding before graft or substitute placement.

Finally, labial soft tissue coverage is typically done with sliding upper lip sulcus flaps, allowing any lateral relaxing incisions to heal by secondary intention. This lateral site should avoid Stensen's duct. Some authors recommend against this technique, because scarring at the lateral donor site can cause periodontal scarring that can lead to problems with future prosthetic bridges or periodontal health, which may necessitate scar release or vestibuloplasty. This problem can usually be avoided if the gingiva is maintained over all the teeth between the cleft and donor site. The advantage of a sliding flap is good restoration of specialized keratinized gingival mucosa, permitting normal dental eruption (Fig. 28-3).

Less commonly, the sliding upper lip sulcus flap may be inadequate for closure, and other variations have been proposed, such as transposition flaps, tongue flaps, or facial artery myomucosal flaps. These flaps have the advantage of bringing greater amounts of vascularized soft tissue to aid in closure of the wide cleft alveolus defect, but the disadvantage is that the mucosa and not the gingiva is transposed into the region of tooth eruption. This lack of replacing gingival tissue in the cleft alveolus may need further treatment with additional gingival grafts or flaps to address recession.

Less Common Variations

Some practitioners recommend that for large clefts, osteotomies should be performed to narrow the bony cleft before ABG. Others will fixate the repair with a corticocancellous bone graft from the iliac crest secured with titanium or resorbable hardware—this would usually be recommended only in the skeletally mature patient or at least after the majority of maxillary growth (older than 12 years of age).

Gingivoperiosteoplasty

GPP requires alveolar bone apposition no more than 1 to 2 mm apart, not including the soft tissue. Mucosal hypertrophy can simulate well-appositioned bony edges, and a careful examination is needed to rule out this false apposition.

The goal of GPP is subperiosteal elevation of flaps to create the ceiling (nasal side), floor (palatal side), and anterior (labial side) aspect of the alveolar space. Ceiling and floor flaps are elevated from the vomer and maxillary segment but leave triangular flaps anteriorly to swing labially. These ceiling flaps, floor flaps, and labial flaps can be approximated with absorbable sutures. Posteriorly, dissection should reach the incisive foramen, which is where the ceiling, floor, and sidewalls merge posteriorly.

Our Preferred Techniques

Donor Bone Graft Harvest—Minimal Access Technique

To minimize autograft bone harvest–related morbidity, minimal access bone harvesting techniques have been developed but can be limited by the volume of graft harvested. At the time of surgery, an ICBG is harvested from the iliac crest with a minimal access incision to facilitate a bone graft harvest of 5 ml of autograft using a power-driven trephine (see accompanying video). The procedure begins with a 1.5 to 2.5 cm incision placed inferior and parallel to the anterior iliac crest. After opening and dividing the subcutaneous tissue, the skin, including Scarpa's fascia, is retracted cephalad over the lateral aspect of the iliac crest. Electrocautery is used to incise the cartilage cap and retracted with an elevator. Next, a starting bone tamp is used to create a concave surface to facilitate harvesting of bone. The same entrance site is used with changing angles of approach to harvest multiple cores of graft. Up to 10 ml of graft material can be reliably harvested without creating a secondary contour abnormality of the donor iliac crest.⁵³

Primary Bone Graft Technique: Autograft and Allograft Bone Reconstruction

After autograft harvest, the donor site is checked for hemostasis; a 0.25% bupivacaine impregnated strip of gelatin sponge such as Gelfoam is placed within the donor-site bone defect for pain control, and the wound is closed in layers. Next, the procedure is transitioned to the oral cavity, where medial and lateral gingivoperiosteal flaps are elevated to expose the anterior aspects of the maxillary and alveolar cleft defect. To completely expose the posterior, medial, and lateral walls of the cleft defect, the cleft alveolar fistula is incised from the incisive foramen to the anterior maxilla (Fig. 28-4, A). The fully defined maxillary defect is shaped as a tetrahedron, extending posteriorly from the incisive foramen to the alveolar ridge anteriorly. The roof of the defect is the nasal closure, and the floor is the palatal closure. The base of the tetrahedron is the anterior labial closure area. The alveolar fistula closure is completed by repairing the nasal and oral mucosal layers separately, creating a large pocket in which to place the bone graft material. Demineralized bone matrix mix, consisting of freeze-dried matrix and cortical chips (DBX Mix), is mixed with the patient's autologous ICBG, bringing the total volume of graft to 10 to 15 ml

Fig. 28-4 **A**, The fully defined maxillary defect is shaped as a tetrahedron, extending posteriorly from the incisive foramen to the alveolar ridge anteriorly. The roof of the defect is the nasal closure, and the floor is the palatal closure. The base of the tetrahedron is the anterior labial closure area. **B**, Demineralized bone matrix mix, consisting of freeze-dried matrix and cortical chips (DBX Mix), which will be mixed with the patient's autologous ICBG, bringing the total volume of graft material to 10 to 15 ml per side. **C**, The allograft/autograft mix is placed within the cleft defect, including the entire pyramid-shaped defect and piriform rim, after ensuring hemostasis and watertight mucosal closure. **D**, The gingivoperiosteal flaps are reapproximated with suture over the grafted site with incision of the periosteum vertically at the level of the first permanent molar to increase mobility of the lateral flap.

per side (Fig. 28-4, *B*). After hemostasis and watertight mucosal closure are secured, the allograft/autograft mix is packed within the cleft defect, taking care to ensure adequate grafting of the entire pyramid-shaped defect, including the piriform rim (Fig. 28-4, *C*). The gingivoperiosteal flaps are reapproximated with suture over the grafted site, incising the periosteum vertically at the level of the first permanent molar to increase mobility of the lateral flap (Fig. 28-4, *D*). When appropriate, Coe-Pak (GC America) is placed over the incision lines as a surgical dressing.

Revision Bone Graft Technique: Allograft-Only Bone Reconstruction

The revision allograft-only procedure begins and ends in the oral cavity, where medial and lateral gingivoperiosteal flaps are elevated to expose the anterior aspects of the maxillary and alveolar cleft defect (see accompanying video). To completely expose the posterior, medial, and lateral walls of the cleft defect, the residual cleft alveolar fistula requires an incision from the incisive

foramen to the anterior maxilla. The fully defined maxillary defect is shaped as a tetrahedron, extending posteriorly from the incisive foramen to the alveolar ridge anteriorly. The roof of the defect is the nasal closure, and the floor is the palatal closure. The base of the tetrahedron is the anterior labial closure area.

The best way to close the alveolar fistula is to repair the nasal and oral mucosal layers separately, thereby creating a large pocket in which to place the allograft bone graft material. After hemostasis and watertight mucosal closure are secured, demineralized bone matrix mix, consisting of freeze-dried matrix and cortical chips (DBX Mix), is packed in the residual alveolar cleft defect with a total graft volume of 2 to 7.5 ml per side as needed. The bone graft material is packed within the cleft defect, filling the entire tetrahedral-shaped defect up to the border of the piriform rim.

The gingivoperiosteal flaps are reapproximated with suture over the grafted site; care is taken to incise the periosteum laterally and therefore create a lateral relaxing incision at the level of the permanent first molar to increase mobility of the lateral flap and diminish tension at the suture line. When appropriate, Coe-Pak is placed over the incision lines as a surgical dressing.

POSTOPERATIVE CARE

Three main issues arise for postoperative care: (1) maintaining bone position (palatal expansion) while the bone is healing, (2) avoiding injury to the soft tissue flaps, and (3) preventing infection of the grafted material. Maintaining bone position can be achieved with orthodontic support, such as an orthodontic wire or a postoperative splint or expander that does not put pressure on the flaps. Injury to the soft tissue can be avoided by restricting the diet to soft foods for 4 to 6 weeks. The use and efficacy of postoperative oral antibiotics or chlorhexidine mouthwash are currently understudied and stochastic at best. We use perioperative antibiotics, typically a cephalosporin, for up to 1 week because of the large graft volumes placed transorally.

Orthodontic movement and further palatal expansion are usually recommended after 4 to 6 months, which is the typical time for initial bony healing. However, some practitioners recommend earlier movement to stimulate the bone with tension on the bone. Regular clinical follow-up and dental imaging are needed to monitor outcomes, including bone graft volume, dental parameters such as root recession, and other complications.

We recommend that patients be discharged when they can tolerate a full liquid diet, usually within 24 hours. The liquid diet is continued for 2 weeks, followed by a soft diet for 4 additional weeks, and finally a normal diet is allowed at 6 weeks after surgery. A form of alveolar segment stabilization after grafting is ideal with either a tooth-borne splint or maintenance of the existing transpalatal arch. The transpalatal arch can remain in place during surgery but can be removed to facilitate closure. It is replaced postoperatively to prevent premature collapse of the alveolar-maxillary segments.

TREATMENT OUTCOMES AND COMPLICATIONS

Minor complications include suboptimal wound healing, such as wound dehiscence, exposure of bone, and sequestration of nonvascularized bone fragments. These complications can be treated without reoperation, usually by diet restriction and improved oral hygiene, including mouthwash and oral antibiotics. Occasionally, debridement of nonincorporating bone graft material is necessary to support wound healing. In general, wound care and coverage with antibiotic ointment or periodontal dressing (for example, Coe-Pak) will result in healing but often with diminished bone graft volume. Rarely, patients may have infections that require operative debridement.

Outcomes on Autograft/Allograft Bone Grafting

More commonly, outcome variables such as bone graft take and longer-term maintenance can be problematic. Multiple studies have examined bone height, such as the Enemark classification and canine tooth eruption rates, with optimal outcomes in the autograft groups.^{43,59} We have reported our experience with autograft only (group 1), autograft with supplemental allograft (group 2), and allograft only in revision cases (group 3).⁷ We achieved favorable results with our preferred technique that uses minimal access bone grafting with supplemental allograft in first-time bone graft reconstruction cases and an allograft-only reconstruction in revision bone graft cases.⁷ We also demonstrated superior results when compared with traditional open ICBG bone grafting of the cleft alveolus. In group 1, ICBG alone, 22 patients (12 males and 10 females; average age 10 years) were treated between October 2004 and December 2006; 17 clefts were unilateral and 5 were bilateral ($n = 27$). In group 2, ICBG plus allograft, 14 patients (8 males and 6 females; average age 9 years) were treated between August 2009 and August 2011; 6 clefts were unilateral and 8 were bilateral ($n = 22$). In group 3, allograft alone, 11 patients (6 males and 5 females; average age 13 years) were treated between February 2011 and January 2012; 7 clefts were unilateral and 4 were bilateral ($n = 11$). Average follow-up was 47.5, 12, and 3.5 months, respectively. Average operative time per alveolus was 78 minutes for group 3, compared with 147 and 111 minutes for groups 1 and 2, respectively ($p < 0.0005$).⁵³

When group 3 was compared with groups 1 and 2, the average radiographic follow-up was 47.5, 20.4, and 13.3 months for groups 1 through 3, respectively. Average operative time per alveolus was 78 minutes for group 3, which was shorter than the 147 and 111 minutes for groups 1 and 2, respectively ($p < 0.0005$). Average engraftment reported by Enemark scores was 1.0 in group 3, which was better than the 2.0 in group 1 ($p < 0.005$) and similar to the 1.1 for group 2 ($p > 0.05$). Revision ABG with allograft alone improved Enemark scores from 3.7 preoperatively to 1.2 postoperatively ($p < 0.0001$). Hospital stay was 0.9 day for group 3 compared with the 2.4 and 2.7 days for groups 1 and 2, respectively ($p < 0.0001$). Bone graft extrusion occurred in six patients (27.3%) in group 1, no complications occurred in group 2, and a single necrotic central incisor was lost at the time of revision bone grafting in group 3 (9.1%). No wound infections, bleeding requiring transfusion/reoperation, or deaths occurred.⁵³ Table 28-2 provides a summary of our autograft outcomes.

Potential cost increases that were incurred with the use of DBX Mix can be offset by the decreased operative time with our allograft-only technique. The average cost of 5 ml of DBX Mix is approximately \$1000. Operating room costs vary widely and have been reported in the literature to vary from \$21 to \$133 per minute and average \$62 per minute. On average the use of our technique saved 69 minutes ($69 \text{ minutes} \times \$62/\text{min} = \$4278$) per alveolus compared with

Table 28-2 Summary of Autograft Outcomes

Group	Number of Patients	Preoperative Enemark Score	Postoperative Enemark Score	Radiologic Follow-Up	Operative Time/Alveolus (minutes)	Complication Rate (percentage)	Length of Hospital Stay (days)
1: ICBG only	22	4.0	2.0	47.5	147	27.3	2.4
2: ICBG plus allograft	14	4.0	1.1*	20.4	111	0.0*	2.7
3: Allograft only	11	3.7	1.2*	13.3	78*	9.1*	0.9*

*Statistically significant data are in boldface with an asterisk.

traditional ICABG techniques. This represents a potential cost savings of \$3278 ($\$4278 - \$1000 = \3278) per bone graft.⁵³

Outcomes on Biologics

BMP-2 is a commercially available recombinant human protein that induces bone formation where it is implanted, thereby avoiding the need to obtain a bone graft from a donor site.⁶⁰ BMP-2 is potentially advantageous in children, because the small size of the patient decreases the available volume of donor bone graft, reduces the duration of surgery, and eliminates the risk of donor-site complications, such as pain, scarring, or hematoma. More tantalizing, if BMP-2 is placed during one of the other infant cleft surgeries, this could potentially eliminate any future ABG procedures, saving the child from a major operation. Unknown potential disadvantages include impinging maxillary growth that may require jaw surgery to correct or a different clinical bone quality affecting dental eruption or orthodontic tooth movement. The present literature documenting the use of BMP-2 for ABG is plagued with small numbers of patients without control group treatment. We have identified at least five pediatric cleft studies in the literature using PubMed. In 2009 Chin⁶¹ reported pediatric use of BMP-2 on 37 cleft lip and palate repairs, as well as on 6 atypical clefts. All but one patient had successful repairs based on clinical and radiologic examination anywhere between 6 and 25 months. A 2007 study by Herford et al^{62,63} followed 10 patients 4 months after BMP-2 ABR. The percentage of the cleft volume filled with bone postoperatively averaged 71.7% compared with 78.1% in iliac crest autologous bone graft (ICABG) control subjects. Fallucco and Carstens⁵⁶ reported 16 of 17 patients treated with BMP-2 showed increased alveolar bone density as measured in Hounsfield units (HU). The 6-month average postoperative increase was 637 HU versus -83 HU preoperatively.

In 2010 Alonso et al⁶⁴ reported a controlled study of eight patients (ages 8 to 12 years) treated with ICABG versus BMP-2 ABR. CT scans were done 6 and 12 months after surgery. At 6 months, the BMP-2 group showed a bone-filling volume percentage of 59.6% compared with 75.4% for the autograft group. The volume percentage differences between the BMP-2 and autograft groups became statistically insignificant at 12 months, with 75% and 80% reported, respectively. Bone height measurement remained shorter at both the 6- and 12-month intervals. At 6 months, the BMP-2 group had 8.5 mm height versus 13.5 mm height for the control group. Although the difference narrowed at 12 months, bone height for the BMP-2 group was 10.2 mm, whereas it was 13.9 mm for the control group.⁶⁴

In 2008 Dickinson et al¹⁰ published a report describing the use of BMP-2 ABG in adolescent patients (average age 16 years). Nine patients underwent BMP-2 ABR and 11 patients had traditional ICABG. They were analyzed at 1 year with films and CT scans. The authors used a 4-point system based on radiographic fill of the alveolar defect and a 4-point system based on intraoral alveolar ridge healing and alar base augmentation; periapical films used a 5-point system (0 to 4) to rate the bone mineralization among cleft tooth roots. The BMP-2 ABG group scored better than the ICABG group in each of these assessments.¹⁰

In 2013 Francis et al⁵⁷ described the use of BMP-2 encased by demineralized bone matrix putty scaffold (Progenix; Medtronic) in 36 patients and compared them with 19 patients who received traditional ICABG ABG. They found that patients undergoing BMP-2 ABR had 97% successful implantation compared with 84% for patients with ICABG ABG. In the initial BMP-2 ABR group (they separated revision BMP-2 ABR), there was increased radiographic evidence of bone. Finally, the BMP-2 ABR group had less infection and shorter operative times than traditional procedures.⁵⁷

BMP-2 outcomes will need to be studied longer term to answer the question of whether its induced bone formation will provide similar outcomes as autograft and allograft. In addition, timing could be of even greater concern, given that recent animal studies have suggested BMP-2 may induce premature fusion of growth sutures in the juvenile developing skeleton.⁶⁵ Also, reports in spine surgery have found unpredictable location and degree of bone formation.⁶⁶⁻⁶⁹ Therefore BMP-2 may adversely affect growth even more than traditional non-BMP-2 ABR. The senior author (A.Y.L.) was recently awarded a national grant examining a large series of patients at different ages who received BMP-2 ABR, and the results are still pending.⁷⁰

CONCLUSION

Optimal reconstruction of the cleft alveolus remains understudied and at times a technically challenging procedure. With the current controversies regarding timing, choice of bone reconstruction material, choice of soft tissue reconstruction, and complexity of measuring skeletal, dental, and orthodontic outcomes, careful long-term analysis of outcomes will ultimately aid in choosing the most optimal reconstructive algorithm.

KEY POINTS

- The alveolus is the keystone of the complete cleft defect: it is the apex of the maxilla, the site requiring dental restoration, and the region of remaining oronasal fistula after primary cleft lip repair. Successful bone reconstruction of the alveolar cleft will unite the maxilla for future facial skeletal surgery, support dental growth and orthodontic treatment, and close the remaining oronasal fistula.
- The timing of alveolar reconstruction remains controversial, but most studies point to the period of mixed dentition (ages 7 to 9 years) as a reasonable balance between impairing maxillary growth and allowing dental eruption and development through adequate bone. A cleft-craniofacial interdisciplinary approach with the cleft surgeon, pediatric dentist, and craniofacial orthodontist is essential for the preoperative preparation of the patient for surgery and the postoperative use of the new bone.
- Successful ABR requires an understanding of the three-dimensional nature of the defect (platonic solid structure) to create adequate vascularized flaps to line this tetrahedron. Multiple techniques exist for bone reconstruction, including autologous bone graft (autograft), autograft with allograft, allograft alone, and in the future the possibility of combination with biologics.

P-A cephalometric analysis was performed on the craniofacial morphology in a study of 88 Brazilian men with cleft lip and palate (operated and nonoperated). Compared with control subjects, nonoperated bilateral cleft lip and palate (BCLP) and unilateral cleft lip and palate (UCLP) subjects showed remarkable facial deformity, characterized by increased width of various facial parts. Facial morphology of surgically treated BCLP and UCLP patients, however, was very similar to that of noncleft subjects, apart from the immediate cleft region.

The study aimed to provide radiographic evidence of de novo synthesis of bone with recombinant human bone morphogenetic protein-2 (rhBMP-2). In 16 of 17 cleft sites, ISO produced trabecular bone that filled the implantation site both transversely and vertically. Stem cell stimulation with rhBMP-2 per absorbable collagen sponge offered highly effective radiographic and clinical unification of the dental arch without donor-site morbidity. Long-term follow-up studies for this initial cohort are underway to examine information on orthodontic relationships and cephalometrics with CBCT technology.

A resorbable collagen matrix with recombinant human bone morphogenetic protein (rhBMP-2) was compared with a traditional iliac crest bone graft for the closure of alveolar defects during secondary dental eruption. Sixteen patients, ages 8 to 12 years, were selected, and computed tomography was used to assess preoperatively and at 6 and 12 months postoperatively. Bone height and defect volume were calculated and revealed progressive alveolar bone union in all patients. For this select group of patients with an immature skeleton, rhBMP-2 therapy resulted in satisfactory bone healing and reduced morbidity compared with traditional iliac crest bone grafting.

Dental Principles in Maxillofacial Surgery

Brendan Bernhart • Thomas M. Grisius • Stephen B. Baker

Pediatric maxillofacial surgeons must understand occlusion and the role of dental specialties in maxillofacial surgery. Many oral problems seen in the pediatric population can be treated nonsurgically or be resolved when dental specialists are involved in a patient's care. This chapter will focus on the role of dental specialists in optimizing maxillofacial rehabilitation in pediatric patients. We use case examples to demonstrate the importance of dental records to establish the correct diagnosis. Accurate identification of the underlying problem is crucial to develop an appropriate treatment plan, and plastic surgeons must be well informed about which specialists are available to help them achieve the best results for each patient.

BASIC DENTAL TERMINOLOGY

Table 29-1 lists some commonly encountered dental terms and their definitions.

Table 29-1 Common Dental Terms

Term	Definition
Apertognathia	An occlusion characterized by a vertical separation of the maxillary and mandibular anterior teeth, frequently described as <i>anterior open bite</i>
Articulator	A mechanical device that represents the temporomandibular joints and jaws, to which the maxillary and mandibular casts may be attached
Buccal	Pertaining to or adjacent to the cheek
Cast	A plaster replica of the teeth and surrounding tissues; also known as a <i>model</i>
Centric occlusion	The relationship of opposing occlusal surfaces that provide the maximum planned contact or intercuspation
Centric relation	The relationship of the mandible to the maxilla when the condyles are in their most anterosuperior, unstrained positions in the glenoid fossa
Cephalometric radiograph	A lateral radiograph of the head made with precise reproducible relationships between x-ray source, subject, and film
Class I occlusion	The mesiobuccal cusp of the first permanent maxillary molar occludes in the buccal groove of the permanent mandibular first molar
Class II malocclusion	The mesiobuccal cusp of the first permanent maxillary molar occludes mesial to the buccal groove of the permanent mandibular first molar
Class III malocclusion	The mesiobuccal cusp of the first permanent maxillary molar occludes distal to the buccal groove of the permanent mandibular first molar
Distal	Away from the median sagittal plane of the face and following the curvature of the arch
Labial	Pertaining to the lip, especially in reference to the surface of a tooth
Lingual	Pertaining to the tongue, especially in reference to the surface of a tooth
Mesial	Situated toward the midline of the dental arch
Palatal	Pertaining to the palate, especially in reference to the surface of a tooth
Proclination	Anterior angulation of the anterior teeth
Prognathic	Forward position of the mandible in relation to the cranial base
Retroclination	Posterior angulation of the anterior teeth
Retrognathic	The condition of a mandible that is posteriorly positioned in relation to the cranial base

DENTAL SPECIALISTS

Orthodontist

Orthodontics is the dental specialty that focuses on establishing alignment of the teeth and jaws consistent with a balanced facial pattern. Orthodontists have an important role in diagnosis and treatment planning to correct dentofacial deformities and other craniomaxillofacial anomalies. The orthodontist's role is to orthodontically align the teeth and orthopedically position the jaws in a manner that facilitates surgical correction and optimizes occlusion and aesthetics.

Prosthodontist

The prosthodontic subspecialty of maxillofacial prosthetics involves treatment beyond that of the teeth and supporting structures to include prosthetic restoration of the head and neck. Maxillofacial prosthetics is the branch of prosthodontics concerned with the restoration and/or re-

placement of the stomatognathic and craniofacial structures with prostheses that may or may not be removed on a regular or elective basis. Prosthetic treatment can be classified as (1) intraoral, (2) extraoral, and (3) combination defects. Artificial materials are used to fabricate both extraoral and intraoral maxillofacial prostheses.

Maxillofacial prosthodontists are crucial to rehabilitate patients with congenital, posttraumatic, and oncologic abnormalities. A maxillofacial prosthodontist should be consulted at the time of diagnosis to correct or minimize deficiencies in mastication, swallowing, speech, control of saliva, and aesthetics. When surgery and a prosthetic restoration are required, the plastic surgeon should refer the patient for prosthetic evaluation preoperatively to determine the type and design of the restoration based on the configuration of the defect. Optimal prosthetic reconstruction frequently depends on the maxillomandibular relationship and availability of adequate bony support. A team approach to treatment planning is the most efficient method to achieve a favorable result for the patient.

Pediatric Dentist

A pedodontist is a pediatric dentist who maintains the health of primary dentition and prepares for proper eruption of permanent dentition. Some pedodontists also have training in the management of early orthodontic problems. If a child sustains an injury to a primary or permanent tooth, a pedodontist is the most appropriate dentist to manage and follow the patient's injury.

Oral and Maxillofacial Surgeon

Oral and maxillofacial surgeons have surgical expertise with the mouth and jaws. These surgeons frequently perform osteointegrated implant placement, orthognathic surgery, temporomandibular joint surgery, and distraction osteogenesis. Collaboration between an oral and maxillofacial surgeon and the plastic surgeon may be beneficial in select cases.

Endodontist

Endodontists treat injuries to nerves in teeth. The pulp is the neurovascular tissue in the crown of the tooth (the visible portion). The root of the tooth also has neurovascular tissue that goes from the pulp to the apex of the tooth (the end of the root). Injuries may occur as a result of trauma, osteotomies, tumors, or infections. If a tooth has been injured, it may become sensitive to hot, cold, and percussion. An endodontist can determine whether this is a temporary or permanent condition, and if permanent nerve damage exists, a root canal may be performed. This requires removing the damaged nerve tissue from the tooth and placing gutta-percha. After a root canal is performed, a prosthetic crown is made to cover the tooth and provide strength.

Periodontist

Periodontists specialize in treating the bone that supports the roots of the tooth. Inflammation, trauma, postablative defects, alveolar bone grafts, and other surgical sequelae may alter or compromise the bone that surrounds these roots (periodontal bone). Ideally, attached gingiva is on the alveolar ridges and supports each tooth. In trauma cases it is often necessary to approximate loose mucosa over the alveolar ridge to close the wound. The periodontist can perform gingival grafts to restore the normal presence of attached gingiva in these regions. This reconstruction of normal soft tissue anatomy is very important for long-term maintenance of the dentition. Periodontists typically treat adult patients, but in patients in whom atypical periodontal disease exists, it is appropriate to seek a periodontist for a child.

CONCEPTS OF OCCLUSION

Much orthodontic treatment is based on occlusal concepts first described by Edward Angle¹ in the late 1800s. Angle classified occlusion based on the maxillary first molar and its relationship to the mandibular first molar. He described normal occlusion as class I—that is, the mesial buccal cusp of the maxillary first molar occludes in the buccal groove of the mandibular first molar without crowding, spaces, or rotations. Angle's concept of normal occlusion remains accepted today and is the primary occlusal relationship desired in most modern orthodontic cases. It is evident that if the molar relationships are ideal, and the teeth are of proportionate size, the remaining dentition will align in an ideal relationship. Whether class I occlusion should be considered “ideal” is a topic of continuing debate. However, most investigators find this relationship to be the most aesthetically pleasing and “protective” of the dentition, because it minimizes aberrant forces. (Fig. 29-1, *A*)

Angle also classified abnormal occlusal relationships, and these classifications of malocclusion are defined as follows:

Class I: Ideal first molar relationship with malposed, poorly spaced, or rotated teeth (Fig. 29-1, *B*).

Class II: Mandibular first molar positioned distally (posterior) to the maxillary first molar.

The maxillary canine cusp is anterior to the mandibular premolar and canine² (Fig. 29-2).

Class III: Mandibular first molar positioned mesially (anterior) to the maxillary first molar.

The maxillary canine cusp is posterior to the mandibular premolar and canine² (Fig. 29-3).

Fig. 29-1 *A*, Class I ideal occlusion. The mesiobuccal cusp of the maxillary first molar occludes in the buccal groove of the mandibular first molar. *B*, Class I malocclusion.

Fig. 29-2 Class II malocclusion. The mandibular first molar is positioned distal (posterior) to the maxillary first molar.

Fig. 29-3 Class III malocclusion. The mandibular first molar is positioned mesial (anterior) to the maxillary first molar.

Fig. 29-4 **A**, Overjet. The distance between the labial surface of the lower incisor and the labial surface of the upper incisor. **B**, Overbite. The amount of vertical overlap of the incisors.

Although Angle's classification is useful to describe dental relationships, additional clinical descriptions can help to define occlusion. *Overjet* measures the distance between the labial surface of the lower incisor and lingual surface of the upper incisor (Fig. 29-4, *A*). Ideally, the mandibular incisors contact the lingual surfaces of the maxillary incisors at or above the dental cingulum. This measurement often corresponds to Angle's classification. For example, an ideal class I occlusion has 2 to 3 mm of overjet, which is the thickness of the incisal edges of the anterior teeth. A class II malocclusion will likely display excessive overjet, with the maxillary incisors anterior to the mandibular incisors, and a class III malocclusion will likely display a negative overjet, with the mandibular incisors anterior to the maxillary incisors (see Figs. 29-1 through 29-3).

Vertical dental relationships are described in terms of *overbite*. Overbite is the amount of vertical overlap of the incisors (Fig. 29-4, *B*). As previously stated, the incisal edges of the mandibular incisors should contact the lingual surfaces of the maxillary incisors at or above the cingulum, which equates to 2 to 3 mm of overbite. If there is no overlap of the incisors, this is referred to as an *anterior open bite* (apertognathia) and is measured in millimeters of separation² (Fig. 29-5).

Fig. 29-5 Anterior open bite. There is no vertical overlap of the incisors.

Fig. 29-6 Deep bite. There is excessive vertical overlap of the incisors.

Fig. 29-7 **A**, A model view from inside the mouth demonstrating the lingual cusps of the maxillary teeth occluding the corresponding fossa of the mandibular teeth. **B** and **C**, Lingual crossbite. The buccal cusps of the maxillary teeth are lingual to the buccal cusps of the mandibular teeth. **D**, Buccal crossbite. The maxillary teeth are positioned too far buccally, resulting in no occlusal contact.

If there is excessive overlap of the incisors, this is referred to as a *deep bite* and is measured in millimeters of overlap or as a percentage of tooth crown coverage² (Fig. 29-6).

Transverse dental relationships are difficult to quantify, primarily because there is a large variation in the width of the dental alveolar arch from one person to another. With ideal occlusion, the buccal cusps of the maxillary posterior teeth are positioned buccally to the buccal cusps of the mandibular teeth, and the lingual cusps of the maxillary teeth fit in the corresponding fossa of the mandibular teeth (Fig. 29-7, *A*). Most transverse discrepancies are caused by a narrow maxilla and often result in a unilateral or bilateral posterior lingual crossbite² (Fig. 29-7, *B*). Less frequently, the maxillary teeth are positioned too far buccally, where there is no occlusal contact, resulting in a buccal crossbite (Fig. 29-7, *C*).

DIAGNOSIS AND TREATMENT PLANNING

Before a treatment plan can be formulated, an accurate diagnosis of the patient's problem must be established. A diagnosis of complex maxillofacial problems involving occlusion is based on history, physical examination, radiographic examination, and dental casts that are accurately mounted on an articulator.

Patient History

An accurate understanding of the chief complaint is essential to develop a treatment plan. It is important to obtain a thorough medical and dental history from every patient. The dental specialist should obtain a dental history, noting the frequency of and reasons for dental treatment, along with any previous experience with dental prostheses. The surgeon should also obtain a detailed history from each patient. Diseases such as juvenile rheumatoid arthritis, diabetes, and scleroderma may affect treatment planning. If a patient has a dentofacial anomaly, a history of hyperplasia or hypoplasia resulting from a syndrome, traumatic accident, or neoplasm will affect treatment considerations. In patients with a cleft lip and/or palate, surgical history and any previous diagnostic testing are paramount to develop a treatment plan. A history of previous radiation therapy may limit reconstructive options. The clinician should focus on the history of the particular problem, but it is important to be aware of all aspects of the patient's history to minimize potential complications.

Physical Examination

The focus of the physical examination depends on the patient's particular problem. However, in general, certain aspects are frequently evaluated to a degree for any patient with a craniomaxillofacial problem. The soft tissues should be evaluated for availability, pliability, presence of fistulas, and quality. Some patients with soft tissue deficits may be candidates for autologous reconstruction, whereas others may be better suited for prosthetic reconstruction. Soft tissue may be present, but it may not be of the quality necessary for a particular area of the oral cavity. All of these findings are important for the ultimate rehabilitation of the patient.

The skeletal structures should be evaluated for the quantity, quality, and symmetry of bone. Skeletal deficiencies or defects may be replaced with a corticocancellous bone graft or may require a microvascular flap. Inadequate bone volume in the alveolar ridges may be treated by grafting bone or moving the jaws. Although bone may be present, it may not be of adequate quality to receive an osteointegrated implant or prosthesis. If teeth are present, an effort should be made to preserve the alveolar bone in these areas, and bone grafting should be performed in any areas in which inadequate bone exists.

Occlusion should be evaluated for the presence or absence of each tooth and the level of oral hygiene. Angle's classification of the dentition and jaws as well as any occlusal cant is documented. The midlines of the upper and lower incisors in relation to the facial midline are recorded, and any discrepancies are noted. The normal vertical position of the maxilla results in showing approximately 3 to 4 mm of the upper incisor when the lips are in repose. Any deviations from normal are noted and incorporated into the treatment plan.

Radiographic Examination

Radiographs are important to see any pathologic conditions and evaluate the hard and soft tissues of the facial skeleton for reconstruction. Several radiographic options are available, and each has a specific indication.

Cephalometric Radiographs

Cephalometric radiographs are useful to evaluate the relationships of teeth to underlying bone, the upper and lower jaws to one another, and the jaws to the cranial base (Fig. 29-8). These radiographs are most commonly used for treatment planning of orthognathic surgery. However, they are also useful for posttraumatic reconstruction cases in which a jaw discrepancy exists and the surgeon is uncertain of the etiologic factors. In posttraumatic cases, jaw discrepancies could be the result of a preexisting discrepancy, inadequate reduction of the initial injury, or loss of bone that gives the illusion of a jaw discrepancy. Careful review of the cephalometric films in the context of the patient's history and physical examination findings is very useful to determine the true cause of the problem. Cephalometric films are also useful for treatment planning of surgical reconstruction.

Panoramic Radiographs

Panoramic radiographs provide useful information, such as interproximal bone height, quality of bone in the maxilla and mandible, location of plates and screws, sinus configuration, location of the inferior alveolar canal, anatomy of the mandibular condyles and eminences, impacted teeth, missing teeth, and significant areas of dental decay and periapical disease. This is an inexpensive method to document a postsurgical result with minimal radiation to the patient. Some hospitals do not provide these images, but almost all orthodontists have these machines in their offices. An orthodontist on the team can usually provide these images.

Individual periapical and bitewing radiographs provide superior accuracy and definition to evaluate interproximal alveolar bone height between teeth, caries, ill-fitting restorations, and periapical pathologic findings of potential supporting teeth for fixed and/or removable prostheses. These are the best images to evaluate individual teeth and are taken by a dentist in the office. These images are rarely necessary for a plastic surgeon.

Fig. 29-8 Lateral cephalometric radiograph with common landmarks. (*A*, A point: innermost point in the depth of the concavity of the maxillary alveolar process. *B*, B point: innermost point on the contour of the mandible between the incisor tooth and the bony chin. *Gn*, gnathion: center of the inferior contour of the chin. *Go*, gonion: most inferior and posterior point at the angle, it is formed by the ramus and body of the mandible. *Me*, menton: most inferior point on the mandibular symphysis. *N*, nasion: anterior point of the intersection between the nasal and frontal bones. *Or*, orbitale: lowest point on the inferior margin of the orbit. *Pg*, pogonion: most anterior point on the contour of the chin. *Po*, porion: uppermost lateral point on the roof of the external auditory meatus. *S*, sella turcica [midpoint of the sella turcica].)

DentaScan

An increasingly popular radiographic tool for surgeons and restorative dentists is CT imaging with the DentaScan (GE Healthcare) (Fig. 29-9). The DentaScan images the jaws in thin slices in the coronal plane, giving views of each tooth and the surrounding bone in millimeter increments. These images also provide a cross-section of the jaw from third molar to third molar. Each image is numbered so that any location can be precisely identified. This detailed imaging allows a surgeon to accurately determine (within millimeters) the location of the inferior alveolar nerve and the quantity and quality of bone at any location. The DentaScan has proved to be an accurate method for preimplant assessment (Lacan) and evaluation of bone grafts of alveolar clefts. An area of particular relevance for the DentaScan is preparing osteointegrated implants for posttraumatic edentulous patients.

Successful application and interpretation of radiographic findings allow all members of a reconstructive team to identify and address specific concerns that affect a patient's result.

Fig. 29-9 A, The DentaScan is a CT imaging device that allows millimeter measurements of bone in the den-toalveolar region. B, Two-dimensional renderings of the jaws have each representative slice numbered in order. C, Cross-sectional images of the jaws are fabricated and numerically coded to identify the exact location of the image. The quality and quantity of bone in each location can be assessed for placing osteointegrated implants.

Articulation of Dental Casts

Because the extent of tissue abnormalities in oral cavity and jaw relationships is often difficult to see during intraoral inspection, articulated diagnostic casts are essential for planning surgical and prosthetic treatment. These mounted casts provide diagnostic information that may be difficult to obtain from clinical examination alone. *Dental casts* are plaster models of the patient's maxillary and mandibular occlusion that are made by pouring plaster into dental impressions. After the casts have been obtained, they are mounted on an articulator.

An *articulator* is a mechanical instrument, to which maxillary and mandibular casts are attached, that replicates the temporomandibular joints and jaws to simulate mandibular movements. Articulators range in complexity from simple hinge devices to complex instruments that accept three-dimensional dynamic patient registrations. Simple hinge articulators are referred to as nonadjustable, because they are only capable of simple hinge motion, and they do not replicate lateral mandibular movements (Fig. 29-10). Semiadjustable articulators replicate average mandibular movements, such as lateral, protrusive, and *Bennett movements* (lateral shift of the mandibular condyles and articular discs in the direction of the working bite) to varying degrees. Semiadjustable articulators are most suitable for orthognathic surgery, preprosthetic surgery, and maxillofacial prostheses (Fig. 29-11).

Fig. 29-10 The Galetti articulator allows the upper and lower casts to be secured with screws, and the two universal joints allow the clinician to place the casts in various positions. This articulator is useful to place the final splints in orthognathic surgery or to assess dental occlusion as the jaws are moved into different positions.

Fig. 29-11 **A**, The facebow and bitefork provide an accurate method of preserving the maxillary-cranial relationship when mounting the maxillary cast. **B**, Aluwax impression wax is heated in warm water and placed on the bitefork of the facebow. The facebow is attached to the fork, placing the earpieces into the external auditory meatus and the inferior orbital rim marker at the rim. The universal screws are tightened. **C**, The facebow is secured to the articulator with the inferior orbital rim marker at the level of the mounting ring. The maxillary cast is placed so that the teeth index into the wax bite on the facebow. The maxillary cast is mounted on the articulator so that its position simulates the craniomaxillary position of the patient. The mandibular cast is mounted by using an occlusal wax registration from the patient. The articulator is turned upside down, and the mandibular cast is related to the maxillary cast with the wax bite registration. **D**, After the plaster is dry, the articulator is turned back to its proper position, and the patient's casts are in proper position to plan the surgery.

When mounting casts on an articulator, it is desirable to orient the maxillary dental cast in the same direction as the opening axis of the articulator. This relationship is preserved by using a facebow. A *facebow transfer* is a caliper device that records the relationship of the maxillary arch to some anatomic reference point or points and transfers this relationship to an articulator. In most instances, the anatomic reference is the transverse horizontal axis between the condyles and inferior orbital rim. The ear opening is a reference point for most semiadjustable facebows, because it is approximately ¼ inch behind the temporomandibular joint. The facebow is positioned with the caliper ends in each ear and the infraorbital pointer at the inferior orbital rim (see Fig. 29-11, C). The universal joints are tightened, and the facebow is removed.

It is secured to the articulator so that it will support the maxillary cast in the proper position for mounting (see Fig. 29-11, A). The teeth of the maxillary cast index into the wax bite pad on the facebow (see Fig. 29-11, B). An arbitrary mounting of the maxillary cast without a facebow transfer can introduce occlusion errors and compromised aesthetics resulting from incorrect orientation of the cast in an anteroposterior and/or transverse direction. Mounting the maxillary cast on the articulator allows the mandibular cast to be positioned with the aid of a patient interocclusal record (see Fig. 29-11, D). The wax record of centric relation and/or maximum intercuspation is used to relate the position of the lower cast to the mounted upper cast. After the lower cast is mounted, the lateral (right, left) and protrusive (optional) records are used to program the condylar guides of the articulator (standard values for Bennett movement is 15 degrees, and condylar guidance is 30 degrees).

The simplicity and speed with which the necessary facebow, dental casts, and interocclusal records are obtained and transferred to a semiadjustable articulator allow an operator to evaluate occlusion and relationship of the jaws with great precision and without the time-consuming techniques needed for fully adjustable articulators.

CEPHALOMETRICS FOR PLANNING ORTHOGNATHIC SURGERY

Although cephalometric treatment planning is most commonly used for traditional orthognathic surgery, it is also indicated for posttraumatic reconstruction, postoncologic reconstruction, and dental rehabilitation. All malocclusions are a result of an improper relationship of the jaws or the position of the teeth within them. *Cephalometric analysis* of radiographs is a quantifiable method of comparing the relationships of the jaws to the cranial base and each other, as well as the relationship of the maxillary and mandibular dentition. This analysis provides information to identify the anatomic basis for malocclusion.

Cephalometric Analysis

Cephalometric analysis begins by identifying a series of standard anatomic landmarks on a radiograph and either tracing them onto a clear acetate overlay or digitizing them on a computer. The landmarks are chosen to include all of the major components of the face (see Fig. 29-8). Lines are drawn between specific landmarks to create a series of planes and angles that enable vertical and horizontal comparisons. Most analyses include a reference area or line for comparison.

Early anthropometric studies on dry skulls used the Frankfort plane, because it closely resembles the natural head position. The Frankfort plane extends from the upper rim of the external auditory meatus (porion) to the inferior border of the orbital rim (orbitale). The Frankfort plane is still commonly used today, but the landmarks are often difficult to accurately identify on cephalometric radiographs. Another reference plane, popularized by Cecil Steiner in the 1950s,

uses a line drawn from the sella turcica (S) to the nasion (N). These landmarks are easily identified on most cephalometric radiographs, making the S-N plane a common reference plane in various cephalometric analyses.³

Extending a line from the nasion (N) to the anterior maxilla (A point) forms the angle SNA. This angle reveals the anteroposterior position of the maxilla relative to the cranial base. Normative data for white Americans indicate that the SNA angle is 82 ± 2 degrees. Therefore a measurement greater than 84 degrees indicates maxillary protrusion. Similarly, angle SNB (line extending from the nasion [N] to the anterior mandible [B point]) reveals the anteroposterior position of the mandible, with normal being 78 ± 2 degrees. An SNB angle of 74 degrees or less indicates mandibular retrognathia, the most common skeletal dysplasia. An SNB angle greater than 80 degrees suggests mandibular prognathism. Angle ANB, the difference between SNA and SNB, is significant, because it indicates the magnitude of the skeletal discrepancy. An ANB angle greater than 2 degrees indicates that the mandible is posterior relative to the maxilla, which is a class II skeletal relationship; it is more likely to appear as a class II dental malocclusion. Conversely, an ANB angle less than 2 degrees demonstrates relative mandibular prognathism and a tendency toward a skeletal class III relationship and a likely dental class III malocclusion.^{3,4}

By identifying multiple dental and skeletal landmarks, a patient's actual dentofacial dimensions are revealed, allowing easy comparison with population norms. However, the clinician needs to be careful not to rely on any single measurement as a sole indicator of maxillomandibular discrepancies, because individual angles are often affected by other angles. For example, angle ANB is greatly affected by vertical proportions. As the mandible rotates in a clockwise direction, for example, in individuals with long faces, the ANB angle increases. This may falsely indicate mandibular deficiency when in fact if the vertical dimension was normal, the counterclockwise rotation of the mandible would likely indicate a normal anteroposterior position. Therefore the cephalometric analysis should be viewed in its entirety when dentofacial dimensions are evaluated. Computers have enabled the input of many more landmarks, allowing clinicians to use multiple analyses to aid in the diagnosis of these discrepancies.

PRESURGICAL ORTHODONTICS

The goal of presurgical orthodontics is to ideally position the teeth to facilitate a planned surgical procedure. One typically associates a need for orthodontic treatment with elective orthognathic surgery. However, there is a role for presurgical orthodontics with patients undergoing post-traumatic reconstruction who have a dentofacial deformity after initial treatment. The purpose of presurgical orthodontics includes aligning the dentition, establishing proper incisor positions, creating a compatible interarch relationship, and preparing the arch before placement of osteo-integrated implants. Attempts to perform orthognathic surgery without orthodontics often lead to poor occlusion, increased risk of relapse, and insufficient surgical correction.

Most malocclusions develop some degree of dental compensation to disguise the inherent discrepancy. Class II malocclusions often present with the mandibular incisors flared anteriorly to lessen the overjet. Excessive overjet also reduces the contact that the mandibular incisors have with the lingual surfaces of the maxillary incisors, causing them to overerupt. This leads to an excessive curve in the mandibular occlusal plane (Fig. 29-12). Conversely, class III malocclusions often present with retroclined mandibular incisors and flared maxillary incisors (see Fig. 29-3). These compensations must be removed before surgery to eliminate dental interferences that may impede adequate bone positioning. Ideally, positioning the incisors in the alveolar bone requires “decompensating” the dentition and leads to a worsening of the occlusion before surgery.

Fig. 29-12 An excessive curve in the mandibular occlusal plane is often the result of overeruption of the mandibular incisors. The mandibular incisors are free to overerupt passively if they do not contact the lingual surfaces of the maxillary incisors.

Establishing compatible dental arches usually involves coordinating the interarch transverse relationships. Because the transverse width of the mandible and maxilla increases posteriorly, any anteroposterior change in the jaws can create dental interferences or a crossbite. Interarch compatibility is evaluated in the later stages of presurgical orthodontics by hand articulating opposing dental casts. This allows an orthodontist to simulate the postsurgical dental relationship and identifies areas that require adjustment. A new set of dental casts is obtained at each subsequent visit to evaluate the adjustments until the desired occlusal relationship is achieved and the dental arches are compatible.

Stabilizing archwires are placed at least 1 month before fabrication of surgical splints to ensure that the dentition will not change before surgery. Surgical hooks are soldered or securely crimped to the stabilizing arch wire as attachments for fixation wiring.

Dentofacial Orthopedics

Jaw discrepancies occur in all three planes of space and are often apparent from an early age. *Dentofacial orthopedics* involves the use of appliances to control and modify facial growth and development to improve these improper skeletal relationships. Traditional growth modification involves the use of intraoral or extraoral forces applied directly to the teeth to produce indirect skeletal forces aimed at improving the maxillomandibular relationship. Common examples include maxillary expansion (Fig. 29-13, *A*), reverse-pull headgear (Fig. 29-13, *B*), and cervical headgear (Fig. 29-13, *C*). These modalities are largely effective and are an accepted part of contemporary orthodontic practice. However, because the forces are directed through the dentition, there are often unwanted dentoalveolar changes. Bone-anchored titanium miniplates offer a method of applying direct bone-borne forces between the maxilla and mandible and have demonstrated tremendous promise, especially for maxillary protraction.^{5,6} This protocol uses Bollard-style plates that are attached to the zygomatic buttress of the maxilla and between the mandibular canines and lateral incisors and have an attachment that perforates at the mucogingival junction (Fig. 29-14, *A* through *K*). Intraoral elastics are worn between the attachments for 22 hours per day and produces a force vector that anteriorly advances the deficient maxilla and soft tissue.^{5,6}

Osteointegrated Implants

Osteointegrated implants may be the treatment of choice for skeletally mature patients in need of prosthetic tooth replacement. These patients have adjacent teeth with a history of minimal restorative treatment or none at all and bone sites that allow an implant of optimal length, diameter, position, and angulation. To properly place osteointegrated dental implants, one needs to know the proper location of the teeth. In an edentulous patient, it is difficult to see exactly where the teeth will be. The prosthodontist should fabricate a diagnostic waxup of the occlusion to help make this determination. A waxup consists of recreating the missing teeth from wax on articulated plaster casts. After the teeth have been waxed into the proper position, the desired location of the implants can be determined. The implant locations are marked on the plaster cast, and a stent is made that incorporates radiopaque markers at the desired location of each dental implant. The patient wears this stent while undergoing DentaScan imaging so that the proposed location of each implant can be seen on the images. Because the markers are at the implant site, the clinician can determine whether the bone in each location is of sufficient quantity and quality. Also, the maximal implant length can be determined on the basis of measurements obtained from the image. If the desired location of the implant is compromised, an alternate site is selected, or augmentation bone grafting is performed (see Fig. 29-9).

Implant dimensions can be determined by bone mapping, periapical radiographs, CT scans, and dental casts. Implants should be surrounded by 2 mm of bone to prevent outward bone resorption, ensure implant stability and correct labiopalatal implant placement, reduce occlusal stresses to the bone, and allow formation of an acceptable papilla between implant and tooth. The implant platform should be situated 2 mm palatal to the predetermined incisal edge of the final restoration. The restoration can be screw retained if the access hole is lingual to the incisal edge, which allows crown retrievability and aesthetic labial contouring of the crown. At least 2 mm of keratinized gingiva should be present on the crest so that it is also present on the abutment and crown.⁷ Coronoapical placement of the implant is critical to provide a smooth emergence profile of the definitive restoration that is similar to the natural tooth at the same level and gives the appearance of a root prominence.⁸ The thickness of the periodontal type determines the length from the implant to the free gingival margin of the crown. The platform or head of the implant should ideally be 2.5 (thick periodontal types) to 3 mm (thin periodontal types) apical from the desired final labial gingival margin of the definitive crown. Adequate space must exist between the implant platform and opposing dentition for anatomically correct restorations. The interocclusal space between the opposing dentition and top of the implant platform should be at least 6 to 7 mm (that is, 2 mm metal and ceramic, 4 mm abutment height, and 0.5 mm for the abutment collar).⁷

Ideal periimplant aesthetics require preservation of intact underlying bone and adjacent teeth; however, interproximal bone loss is inevitable after tooth extraction, which causes apical migration of the interdental papilla. Implant clinical crowns are usually longer than the original tooth-to-tooth contacts to compensate for the lack of interdental papilla. To avoid technique-sensitive grafting procedures that may be necessary in the presence of inadequate hard and soft tissues at healed extraction sites, current tissue preservation techniques involve immediate replacement of failing teeth (without acute infection or bone destruction) with provisional implant restoration. Studies have shown that immobile immediate provisional restorations can enhance soft tissue management by supporting the periimplant mucosa and maintaining papilla height and gingival outline. Delayed implant placement requires several months of treatment but can produce equivalent results if the bone support is intact, length of treatment is reduced, and number of surgical procedures is reduced. The overall success rate for immediate implant placement is 94.6% compared with 94.4% for implants placed at healed sites.⁹

Research over the past decade has helped to predict achievable papilla height between two teeth, between teeth and implants, and between adjacent implants in the maxillary anterior segment. It is recommended that the clinician provide an adequate mesiodistal distance of at least 1.5 to 2 mm between an implant and adjacent tooth and at least 3 to 3.5 mm between two implants to prevent interimplant crestal bone loss resulting from the crossover of angular defects.¹⁰ If the two maxillary central incisors are replaced with two implants, a 4 to 4.5 mm distance is recommended.¹¹ Interdental papilla completely extending up to the contact point between two natural teeth is directly related to the distance between the contact point and the interdental crest of bone. It has been reported that the papilla is present 100% of the time if the distance between two teeth is 5 mm or less; however, the papilla was present 56% of the time at a distance of 6 mm.⁸ Papilla reform predictably between an implant and a natural tooth when the distance from the crestal bone to the contact point is 4.5 and 3.5 mm between adjacent implant restorations. The greatest vertical soft tissue height can be achieved between a tooth and a pontic (6.5 mm) and between adjacent pontics (6.0 mm) without proximity limitations.¹² These distances should be considered when placement of implants and/or pontics is determined during restoration of single or multiple missing teeth in the aesthetic zone. Implants with smaller diameters at the implant-abutment interface or fewer implants with pontics may be necessary to maintain the papilla and improve the aesthetics of multiple missing teeth in the aesthetic zone.

Prosthetic Replacement of Missing Teeth

Patients with clefts of the alveolar processes and palate may have missing teeth (that is, lateral incisors) and deficient soft and hard tissue requiring surgical reconstruction. It is possible to replace a single tooth in the aesthetic zone with a removable (interim/transitional) partial denture, a fixed partial denture/bridge, or an implant-supported crown. When choosing the type of prosthesis, the following factors must be taken into consideration: patient age, skeletal growth, occlusion, periodontal status, tooth eruption patterns, orthodontic treatment, quality and quantity of hard and soft tissue, oral hygiene, psychological state, and patient preference for removable or fixed prostheses. Osteointegrated implants are usually the treatment of choice for skeletally mature patients when anterior teeth neighboring the edentulous space have had minimal or no restorative treatment. A removable appliance is recommended for pediatric patients with tooth loss, because the prosthesis can be adapted and adjusted easily according to growth, dental changes, and bone grafting procedures to the edentulous area. Secondary bone grafting to support or augment maxillary segments is beneficial for definitive prosthetic treatment during early adulthood, because it allows a reduction in the length of fixed partial dentures (fewer abutments) and provides adequate quantity and quality of bone when the prosthodontist is considering placement of an osteointegrated implant. To deliver an aesthetic restoration and provide an optimal occlusal scheme for a patient, an orthodontist should be consulted to ensure the completion of maxillary and mandibular growth and orthodontics before the fabrication of definitive fixed partial dentures/bridges and implant-supported restorations.

Resin-bonded fixed partial dentures for single tooth replacement are a minimally invasive treatment option for patients in their late teens or in adulthood who may opt not to have implants or conventional fixed partial dentures, those who are not candidates for implant-supported restorations (because of incomplete skeletal growth, lack of hard/soft tissue, medical or psychological issues, or local adverse conditions), or those who desire an aesthetic fixed restoration requiring little or no preparation of neighboring teeth before additional bone grafting and/or implants. Composite and ceramic resin-bonded fixed partial dentures provide superior aesthetics for traditional cast metal resin-bonded fixed partial dentures, or “Maryland bridges,” because of the absence of cast metal that often causes discoloration of abutment teeth in translucent areas.

CASE EXAMPLES

The following two patients demonstrate how the preceding concepts were used to manage complex cases that involved occlusion.

The first patient was a young woman who sustained major maxillofacial trauma that included injuries to her mandible, maxilla, and bilateral orbit and malar regions. The maxillary injury included loss of her anterior teeth and a major avulsion of alveolar bone. The plain radiograph showed the location of her plates after fixation (Fig. 29-15, *A*). Because the patient had lost anterior maxillary bone, it was uncertain whether the apparent class III malocclusion was the result of bone loss or skeletal malocclusion. Articulated models were used with cephalometric analysis to determine whether the maxillomandibular relationship was normal and the cause of the deficient maxilla was the result of avulsed bone.

The malunion of the mandible required treatment, and the articulated models were used to perform model surgery in preparation for the mandibular osteotomy (Fig. 29-15, *B*). A temporary maxillary prosthesis was also fabricated by the prosthodontist (Fig. 29-15, *C*). The mandible was moved into the ideal position and secured with rigid fixation (Fig. 29-15, *D*). Because osteointegrated implants were to be placed, an orthodontist aligned the arches before implant placement (Fig. 29-15, *E*).

Fig. 29-15 *A*, Postoperative radiograph of the patient after panfacial fracture. *B*, Facebow-mounted dental records showed an inadequate reduction of the mandibular fracture. These records were also used by the orthodontist to determine how much orthodontic movement was needed to achieve class I occlusion. *C*, Postmodel surgery records with temporary dental prosthesis in place.

A DentaScan was used to determine the amount and location of bone to be grafted (Fig. 29-15, *F* through *H*). Corticocancellous bone from the iliac crest was used to augment the anterior maxilla and nasal floor in preparation for the implants (Fig. 29-15, *I*). A vestibuloplasty with a split-thickness skin graft was performed to extend the buccal vestibule and improve the soft tissue in the region of the anticipated implant abutments (Fig. 29-15, *J*).

Fig. 29-15, cont'd **D**, Postreduction view after posttraumatic orthognathic surgery. **E**, Patient as she appeared during the extended treatment phase. **F**, Patient's DentaScan and records showed that her class III appearance was the result of avulsive bone loss at the anterior maxilla rather than incorrect reduction of fractures. **G** and **H**, DentaScan images showed the maxillary dental arch with numbered images. For this patient, imaging was done with a surgical stent containing radiopaque markers at the planned location of each implant. The markers allowed the surgeon to key in on the exact numbered image to assess bone quality and density.

The implants were ready to be placed 6 months after the bone grafting. The desired implant location was determined from the temporary prosthesis. It is important to position the implants in the center of the desired location of the tooth to avoid compromising dental aesthetics by having an implant that is visible between the teeth. A surgical stent was fabricated to indicate the exact location of each implant during surgery (Fig. 29-15, *K* through *L*). The implants were placed in a minimally traumatic fashion under copious irrigation (Fig. 29-15, *M*). As each implant was placed, a pin was placed to facilitate parallel positioning of all of the implants (Fig. 29-15, *N* and *O*).

The final periapical radiograph of the implant showed good bone apposition with minimal resorption of bone (Fig. 29-15, *P*). Finally, the patient's smile can be appreciated after final cementing of the prosthesis onto the implants (Fig. 29-15, *Q*).

Fig. 29-15, cont'd **I**, Corticocancellous iliac crest bone was placed in the maxilla to augment the osseous volume required for osseointegrated implants. **J**, A skin graft was used to re-create the normal vestibular depth after the bone grafts were placed. **K**, Surgical stent fabricated by the prosthodontist to show the surgeon the exact location and angulation of each implant. **L**, The stent in place showing where the implants will be placed. **M**, The implants were placed with a low-speed drill and irrigation. **N**, Implants showing parallel placement. **O**, Implants at the second stage before transmucosal abutments were placed. Fig. 29-16 A, This young, partially edentulous woman had undergone bilateral cleft lip and palate repair and desired osteointegrated implants. B, The prosthodontist's surgical stent was used by the surgeon to ensure placement of the implant in the desired position. C, Temporary prosthesis that the patient wore while the implants were undergoing osteointegration. D, Second-stage application of the transmucosal posts to which the final prosthesis was secured.

This 22-year-old woman had undergone a bilateral cleft lip and palate repair and was seen for prosthetic reconstruction of her upper lateral incisors (Fig. 29-16, A). DentaScan imaging revealed insufficient bone for dental implants, so she underwent supplemental alveolar bone grafting 6 months before the implants were placed. Her dental casts were articulated, and the ideal form of the lateral incisors was created from wax on the maxillary cast. From the diagnostic waxup, a surgical stent was fabricated from light-cured acrylic (Triad System; Dentsply). A crestal gingival incision was reflected with a No. 9 periosteal elevator, and a surgical stent was placed in the mouth to show the surgeon the ideal location and inclination of the osteointegrated implants (Fig. 29-16, B). The implants were placed according to the manufacturer's protocol (Southern Implants), and the temporary prosthesis was used for 6 months while the implants osteointegrated (Fig. 29-16, C). The second stage required placing the abutments, which are transgingival posts that screw into the implants and secure the final prosthesis (Fig. 29-16, D).

PROSTHETIC CONSIDERATIONS FOR PEDIATRIC ONCOLOGY PATIENTS

Surgical considerations, such as preservation of the hard palate where possible, retention of key teeth, incision location and resections relative to specific teeth, use of split-thickness grafts, and elimination of tissues that will be rendered nonfunctional postoperatively, should be discussed before surgery to enhance the prosthetic prognosis without compromising tumor removal. It is

Fig. 29-17 A, This patient had a tumor removed in childhood. His ultimate reconstruction required osteointegrated implants. A removable obturator was fabricated, allowing good function until growth was complete. B, The obturator fits with vacuum suction and mechanical undercuts to the maxilla. C, The final restoration in place. D, The surgical cut was made very close to the tooth, compromising periodontal support. It was recommended that the tooth be extracted at the surgical margin to allow optimal bony healing. This minimizes subsequent periodontal disease.

important to preserve the hard palate and alveolar processes, because this allows support of the prosthesis and possible fabrication of an implant-supported restoration (Fig. 29-17). Maintaining the premaxillary segment is critical for appearance (that is, dental aesthetics and lip support), and this segment is the most effective site for implant placement for edentulous patients. Removable maxillofacial prostheses with attachments on the tissue side may be fabricated to seat over a bar splinting multiple implants or individual implants. The preservation of the arch form allows greater anteroposterior spread of implants, which contributes to greater retention of the obturator prosthesis during speech and function.

Obturation of palatal defects is enhanced when there is healthy periodontal support and multiple teeth are present on both sides of the arch to provide cross-arch stabilization for interim and definitive obturator prostheses. In many patients, the tissue is compromised because of the location and extent of the resection; however, the surgeon should take into account clasping of key teeth such as the cuspid and bony support of the hard palate to provide greater retention, support, and stability of the prosthesis (Fig. 29-17, A through C). Healthy periodontal support of the cuspid and its location at the corner of the maxillary arch are important for retention of a prosthesis and lip support. The lateral incisor is a poor tooth to clasp because of its smaller root and lack of bony support, which may lead to greater mobility of the tooth if it is used to retain a prosthesis. The surgeon should be mindful of the location of the transalveolar resection, because resections through the transseptal bone between teeth have a negative impact on the bony support, mobility, and vitality of the remaining teeth adjacent to the resection (Fig. 29-17, D).

To preserve bony support of the teeth, resections should be made after extraction of the next distal tooth, as far as possible from the tooth adjacent to the defect and through the distal portion of the socket.¹³

The surgeon can contribute to additional forms of obturator retention and tolerance by lining a split-thickness skin graft to the internal cheek surface of the defect and linings within the defect to support modest applications of pressure.¹⁴ Obturator prostheses should engage the scar band superiorly and inferiorly to enhance stability, support, and retention. A split-thickness graft may also be considered to cover the medial margin of the palatal bones when there is inadequate palatal mucosa.¹⁵ Engaging the medial wall of the defect can increase retention of the obturator, which is particularly important when remaining teeth are compromised or alternative forms of retention are inadequate.

The surgeon should remove the entire soft palate on the resected side if less than 1 cm of the posterior one third remains and the patient has teeth remaining for adequate retention and support of a prosthesis. The nonfunctional band of soft palate will contract superiorly, making it difficult to seat or remove the prosthesis, and adequate velopharyngeal closure will be difficult. Speech may be hypernasal, and leakage of foods and liquids into the nose may occur during swallowing if the soft palate remnant prevents optimal placement of the prosthesis for restoring palate-pharyngeal function.¹⁶

Obturator Prostheses

Obturator prostheses are indicated for patients with congenital or acquired tissue openings, primarily of the hard palate and/or contiguous alveolar structures¹⁷ (Fig. 29-18). Obturator prostheses may require an additional speech aid component to prosthetically manage velopharyngeal insufficiency resulting from defects of the hard and soft palates. An obturating prosthesis can be a removable partial denture, a complete denture, an overdenture, or an acrylic resin stent without tooth replacement. The objective of prosthetically restoring palatal defects is to provide the pa-

Fig. 29-18 A, This patient had a large anterior hard palatal fistula that had failed local flap repair once previously. He had not undergone maxillary expansion. B, The cast shows the large fistula just posterior to the incisive foramen. C, The team prosthodontist fabricated a palatal expander that also served as a fistula obturator. This allowed the patient to function normally while the maxilla was expanded. Definitive fistula repair was undertaken after maxillary expansion.

tient with a prosthesis that is comfortable, reestablishes the oral-nasal partition, allows control of resonance and nasal emissions during speech, prevents leakage of foods and liquids into the paranasal sinuses, restores mastication, provides support for the lip and cheek, and is acceptable in appearance. This is especially relevant for providing children with normal function and appearance when surgery needs to be delayed for reasons such as completion of chemotherapy, cessation of growth, or postponing major surgery until the summer. A pressure-resistant seal of the interim and/or definitive obturator bulb against the mucosal lining and skin graft provides physical separation between the oral and sinus cavities necessary to restore speech and swallowing. Normal or near-normal levels of function and aesthetics can be achieved for most patients, with hard palate defects restored with definitive prosthodontic treatment.^{18,19}

There are three phases of prosthetic rehabilitation: surgical, interim, and definitive obturation. The first phase, *surgical obturation*, requires placing the prosthesis at the time of surgery to maintain oral function during the initial postoperative period. The prosthesis is fabricated on a cast made from a preoperative impression. It is possible to retain the prosthesis with either wrought wire clasps or ligature wires. For completely edentulous patients, ligature wires are threaded through the alveolus after penetration of the alveolus with an awl, drill, or 18-gauge needle tap corresponding to the wire openings in the prosthesis. The wires are tightened completely with a clockwise rotation, cut, and twisted interproximally for dentulous patients or twisted back into the wire openings/recesses for edentulous patients. The immediate surgical prosthesis is used for 7 to 10 days, helps the healing process, and prevents scar contraction.²⁰

An *interim obturator* provides patients with a comfortable and functional prosthesis until healing is complete. This prosthesis is most commonly made on a cast from a preoperative impression and is available for insertion when the immediate obturator and surgical dressing are removed. Delivery of an interim prosthesis provides physiologic, hygienic, and psychological support for patients. An impression can be made when the surgical obturator and surgical dressing are removed, but this may delay insertion of the interim obturator and cause increased anxiety because of cosmetic and functional deficiencies. Lack of early obturation of the defect may lead to collapse of tissue around the defect, which may compromise facial aesthetics and complicate future rehabilitative care. An interim obturator is commonly worn for 3 to 4 months for dentulous patients and for 6 months for edentulous patients until healing is sufficient to allow fabrication of a definitive obturator. Additional factors must be considered before fabrication of a more permanent restoration, such as the patient's tissue response to radiation and/or chemotherapy, the size of the defect, progress of healing (soft/hard tissues), presence or absence of teeth, potential for future growth before placement of osteointegrated implants, and effectiveness of the present obturator.

A definitive obturator is indicated when the hard and soft tissues show clinical signs of health and appear stable postoperatively and should only be considered when craniofacial growth has ceased. Definitive obturator prostheses for partially edentulous patients (Fig. 29-19) are similar in construction to definitive removable partial dentures. A definitive obturator provides prosthetic tooth replacement and consists of denture acrylic that is heat processed to a rigid cast metal framework with clasps and cast fittings that fit into prepared surfaces of the teeth for selected teeth to retain and support the prosthesis. An existing denture can be rebased or relined postoperatively, or a new denture/obturator may be fabricated for edentulous patients (Fig. 29-20). A patient's ability to function with (that is, speak, swallow, and masticate) and tolerate the existing interim obturator may provide an indication of prosthetic outcome with a definitive prosthesis; however, the clinician must take into account the prosthetic limitations of an interim prosthesis.

Fig. 29-19 A, Large postoncologic defect in the maxilla of a teenage patient. The growing patient could not have implants placed, so a prosthesis was fabricated to provide normal form and function. B, Prosthesis showing mechanical undercuts and clasps. C, Prosthesis in the maxilla. D, Patient's final occlusion.

Fig. 29-20 A, This adult patient had previously refused to undergo cleft palate repair but subsequently presented for treatment. B, The prosthesis was designed to obturate the cleft palate and use its undercuts to provide retention. C, Patient's occlusion with the prosthesis in place.

Speech Aid Prostheses

Speech aid prostheses (*soft palate obturators*) are maxillary, removable prostheses indicated for restoring acquired or congenital/developmental aberrations (Fig. 29-21) of the soft palate, with the posterior portion extending into the pharynx to separate the oropharynx and nasopharynx during phonation and deglutition, thereby completing the palatopharyngeal sphincter.¹⁷ Speech aid prostheses are indicated for selected patients diagnosed with velopharyngeal insufficiency (see Chapter 23). It is a condition in which there is a lack of effective closure between the soft palate and one or more of the pharyngeal walls during swallowing or speech sounds that require high intraoral pressure. Patients present clinically with nasal reflux, escape of air during speech, hypernasality, and compromised swallowing. The lack of closure may be the result of palatopharyngeal insufficiency, incompetence (inadequate elevation of soft palate movement), or lack of pharyngeal wall movement.

A speech aid prosthesis helps patients to eliminate nasality, nasal emissions into the defect, and regurgitation of food into the nasopharynx. The prosthetic bulb extends to the posterior pharyngeal wall at the level of the palatal plane and median tubercle of C1 and is functionally developed and modified according to the confines of the muscles of the lateral and posterior walls.²¹ Evalu-

Fig. 29-21 A, Patient with a soft palate missing some of its posterior tissue. B, Appliance designed to replace the deficient soft palatal tissue with acrylic, which provides posterior velopharyngeal competence. C, The appliance in the patient's mouth with the posterior extension that augments the posterior edge of the soft palate.

ation by a speech pathologist is recommended for patients in whom velopharyngeal function is restored, but speech articulation is poor. Speech therapy is extremely important for patients with a cleft palate and compensatory speech patterns, because speech aid prostheses do not eliminate these habits affecting speech. The prosthodontist should consider videofluoroscopy and nasal and oral endoscopy when a prosthesis is fabricated to ensure adequate palatopharyngeal closure for patients presenting with palatopharyngeal insufficiency or incompetence.²²

Palatal Lift Prostheses

Palatal lift prostheses are removable prostheses that can be used as temporary or definitive treatment for palatal incompetence (Fig. 29-22). Velopharyngeal closure is achieved by prosthetic elevation of an incompetent soft palate that is dysfunctional as a result of clefting, surgery, trauma, stroke, or paralysis from an unknown cause. Postoperative scarring after palatoplasty, traumatic brain injuries, cerebral palsy, and injury to the soft palate may cause palatal incompetence. A palatal lift prosthesis differs from a speech aid prosthesis, because it does not extend into the pharynx to restore palatopharyngeal function. The palatal lift elevates the soft palate (adequate length and size) both superiorly and posteriorly to achieve soft palate closure with the peripheral pharyngeal tissues, thereby improving voice quality by increasing oral pressure for consonant articulation and reducing hypernasality and escape of nasal air. Prosthetic stimulation of the soft palate muscles is recommended as soon as palatal paralysis is noted to prevent palatal disuse atrophy. The prosthetic–physical therapy may progress to the point where adequate elevation of the soft palate can be achieved without the prosthesis.²³

Completion of a palatal lift prosthesis may require numerous visits over several months to provide successive additions to the prosthesis to offset tissue tolerance problems on the soft palate and allow the patient to adjust to wearing the prosthesis. It is recommended that the prosthodontist and speech pathologist work together to fabricate the prosthesis to achieve optimal rates of nasal airflow and intraoral air pressures during speech production. Although some clinicians use palatal lift prostheses with the rationale that the palatopharyngeal port function will improve over time as the prosthesis is worn, it appears unwarranted to routinely expect permanently im-

Fig. 29-22 A, A palatal lift, which elevates the posterior portion of the soft palate if incompetence is observed. It can be frequently adjusted or reduced, allowing the patient to achieve normal resonance. B, The appliance can be seen extending back under the soft palate where it elevates this structure and helps it to achieve normal function.

proved palatopharyngeal function during speech production to the point that the prosthesis may be discontinued.²⁴

Commissure Splint Therapy

Treating traumatic injuries to the commissure, such as injuries resulting from electrical or thermal burns, is a challenge for both plastic surgeons and dentists. *Commissure splint therapy*, in association with surgery, has been effective to reduce the effects of scar contracture from oral and perioral burns that can result in cosmetic deformities of the commissure, microstomia, obliterated vestibules, tongue ankylosis, and compromised mastication and speech. Dental deformities associated with contracture have also been documented; these include crossbite, crowding, retrusion, palatal arch contracture, lingually inclined mandibular teeth, and mandibular arch contracture.

A prosthodontist should fabricate and deliver commissure splints within days of any trauma to prevent microstomia, considering that wound margins begin to contract 5 days after injury. The prosthesis consists of an acrylic stent with acrylic conformers curving laterally and posteriorly to retract the corners of the mouth to simulate the desired contours of the commissures. The prosthesis is worn 24 hours a day for 6 to 8 months with an additional 4 to 6 months of nighttime wear.²⁵

Auricular Prostheses

Extraoral prostheses may be the treatment of choice for patients who do not want to undergo surgery, patients with defects that cannot be predictably reconstructed surgically, or as an interim prosthesis if surgical reconstruction must be delayed. The prosthetic rehabilitation of auricular defects, both congenital and acquired, requires consultation with a plastic surgeon to determine whether an acceptable surgical result can be achieved. Silicone elastomers and other synthetic materials have made it possible to fabricate natural-appearing prostheses. Temporary prostheses made of heat-polymerizing acrylic may be fabricated and delivered to the tissue bed 3 to 4 weeks after surgery. Acrylic resin prostheses allow periodic adjustment and relining with denture soft reline material to accommodate changes in the soft tissue.

If reconstruction is not anticipated, the auricle and any remaining tissue tags should be removed to improve retention of the prosthesis, positioning and contour relative to the tragus, and ease of placement by the patient. The tragus should be retained or surgically reconstructed, if necessary, to conceal the anterior tissue margin of the prosthesis. After complete resection of the auricle, a nonmobile, flat tissue bed lined with split-thickness skin, full-thickness skin, or a pedicle flap provides the most favorable base for an auricular prosthesis. Flaps containing hair should be avoided, because most auricular prostheses are retained with adhesives, and hair complicates cleaning implant components in implant-supported prostheses and interferes with margin integrity.

Defects resulting from the partial resection of the auricle or microtia are more difficult to restore prosthetically. The margins of a prosthesis tend to be more visible, and patients may experience greater difficulty orienting a prosthesis over a partially retained ear, which may be malformed.

Medical grade adhesives are often used to retain auricular prostheses; however, some patients may encounter problems, such as retention, skin irritation, and prosthesis misalignment. The use of bone-anchored osteointegrated implants to retain an extraoral prosthesis can eliminate retention problems and provide aesthetic restoration.

Trismus Rehabilitation

Patients must consult with a reconstructive surgeon before they begin a postoperative exercise program for the mandible. Patients should perform mandibular exercises multiple times each day, and progress should be documented by the patient, physical therapist, and prosthodontist. Maximal opening of the mandible with movement away from the operated side loosens scar tissue, reduces trismus, and improves the patient's ability to achieve a more normal maxillomandibular relationship. Devices are available to counteract limited jaw opening during the immediate post-surgical period, minimize contracture of scar tissue, strengthen jaw muscles, and mobilize the joints. A simple and inexpensive technique is to use tongue blades to gauge the degree of mouth opening between the anterior teeth and repeat this several times during the day. A threaded, acrylic, tapered screw can also be used, which can be alternately placed on the anterior or posterior teeth and gradually turned to increase opening of the jaw. Commercial devices, such as the TheraBite Jaw Motion Rehabilitation System (Atos Medical) or the Dynasplint System (Dynasplint Systems), are available to mechanically assist restoration of proper jaw opening. These devices allow a patient to comfortably control the degree of opening with repetitive passive motion, stretch the jaw in an anatomically correct pattern, and measure the degree of opening.

CONCLUSION

The application of principles in orthodontics and maxillofacial prosthetics has many indications in pediatric maxillofacial surgery. It is our hope that this chapter informs the reader of the available resources of his or her dental colleagues. The growing pediatric patient with a mixed dentition may not be a candidate for a definitive surgical solution. Frequently maxillofacial prosthetics provide an excellent alternative to a surgical procedure that creates both an aesthetic and functional result. Additionally, the specialty of orthodontics continues to improve the ability to modify the facial skeleton orthopedically using advanced designs in headgear and skeletal anchorage. Knowledge and application of these advances and principles to the pediatric population will help ensure that each patient achieves the best result for their clinical problem.

KEY POINTS

- Many oral problems seen in the pediatric population can be treated nonsurgically, and treatments may be enhanced when appropriate dental specialists are involved in a patient's care.
- For patients requiring surgery and prosthetic restoration, the plastic surgeon should refer the patient for prosthetic evaluation preoperatively to determine the type and design of the restoration based on the configuration of the defect.

- Angle's concept of normal occlusion remains effective today and is the primary occlusal relationship desired in most modern orthodontic cases. It is evident that if molar relationships are ideal, and the teeth are of proportionate size, the remaining dentition will align in an ideal relationship. Although there is some debate regarding the definition of "ideal" occlusion, most investigators find that this relationship is the most aesthetic as well as "protective," because it minimizes aberrant forces.
- A diagnosis of complex maxillofacial problems involving occlusion is based on history, physical examination, radiographic examination, and dental casts accurately mounted on an articulator.
- Cephalometric radiographs are useful to evaluate the relationship of teeth to underlying bone, the upper and lower jaws to one another, and jaws to the cranial base. Careful review of cephalometric radiographs in the context of the patient's history and physical examination findings is very useful to elucidate the true nature of the problem. It also serves as a useful tool for planning the surgical reconstruction.
- Panoramic radiographs provide useful information, such as interproximal bone height, quality of the bone in the maxilla and mandible, locations of plates and screws, sinus configuration, location of the inferior alveolar canal, anatomy of the mandibular condyles and eminences, impacted teeth, missing teeth, and significant areas of dental decay and periapical disease.
- The DentaScan images the jaws in thin slices in the coronal plane (viewed from third molar to third molar), allowing one to view each tooth and the surrounding bone in millimeter increments.
- The role of presurgical orthodontics varies from early alignment of dentition, establishing proper incisor positions, and creating a compatible interarch relationship, to later preparation of the arch before placement of osteointegrated implants.
- Before deciding which prosthesis should be used, the surgeon must consider the patient's age, skeletal growth, occlusion, periodontal status, tooth eruption patterns, orthodontic treatment, quality and quantity of hard and soft tissue, oral hygiene, psychological state, and preference for a removable or fixed prosthesis.
- Osteointegrated implants are often the treatment of choice for skeletally mature patients when anterior teeth neighboring the edentulous space have a history of minimal or no restorative treatment. A removable appliance is recommended for pediatric patients who have tooth loss, because the prosthesis can be adapted and adjusted with ease according to growth, dental changes, and bone grafting procedures to the edentulous area.

Continued

KEY POINTS (continued)

- Obturator prostheses are indicated for patients who have congenital or acquired tissue openings, primarily of the hard palate and/or contiguous alveolar structures. Obturator prostheses may require an additional speech aid component to manage velopharyngeal insufficiency caused by defects of the hard and soft palate.
- A speech aid prosthesis (soft palate obturator) is a maxillary removable prosthesis indicated for restoring acquired or congenital/developmental aberrations of the soft palate, with a portion extending into the pharynx to separate the oropharynx and nasopharynx during phonation and deglutition, thereby completing the palatopharyngeal sphincter. Speech aid prostheses are indicated for selected patients diagnosed with velopharyngeal insufficiency.
- A palatal lift prosthesis differs from a speech aid prosthesis in that it does not extend into the pharynx to restore palatopharyngeal function. The palatal lift elevates the soft palate (adequate length and size) superiorly and posteriorly to achieve soft palate closure with the peripheral pharyngeal tissues, thereby improving voice quality by increasing oral pressure for consonant articulation and reducing hypernasality and escape of nasal air.
- Extraoral devices such as auricular prostheses may be the treatment of choice for patients who do not want to undergo surgery, for defects that cannot be predictably reconstructed surgically, or if an interim prosthesis is desired before a delayed surgical reconstruction.

Craniofacial Microsomia

Lee W.T. Alkureishi • Rosemary Seelaus • Pravin K. Patel

Three-Dimensional Imaging for Craniofacial Microsomia Patients; Virtual Surgical Planning: Asymmetrical LeFort I Advancement and Bilateral Sagittal Split Osteotomy.

THE NOMENCLATURE OF CRANIOFACIAL MICROSOMIA

Craniofacial microsomia (CFM) comprises the spectrum of craniofacial anomalies that results in underdevelopment of the facial structures affecting the hemiface, either unilateral or bilateral, to a varying extent. These conditions are known by a variety of names because of the wide range of phenotypic expression (Fig. 30-1 and Box 30-1). The names include *first and second branchial arch syndrome*, *lateral facial dysplasia*, *otomandibular dysostosis*, *oculoauriculovertebral dysplasia* (*Goldenhar syndrome*), and within the Tessier clefting classification, a *number 7 cleft*. Patients with unilateral microtia and mandibular deficiency typically are described as having hemifacial microsomia (HFM). However, those who also have epibulbar dermoids and hemivertebral anomalies have Goldenhar syndrome.^{1,2} Some patients have only isolated components within the spectrum, such as preauricular tags and microtia without other obvious anomalies. Similarly, patients may present with lateral facial clefting (macrostomia) without other obvious anomalies or with hemimandible hypoplasia without overlying soft tissue involvement.

Fig. 30-1 The variability in the phenotypic expression of CFM. **A**, Right mandibular hypoplasia (Kaban-Pruzansky type I) (see Table 30-3). **B**, Right mandibular and maxillary deformity and right microtia (Kaban-Pruzansky type IIA). **C**, Right mandibular and maxillary deficiency, right microtia, right marginal nerve palsy, and cervical scoliosis (Kaban-Pruzansky type IIB). **D**, Right mandibular and maxillary deficiency, right orbital dystopia, right microtia, and right macrostomia (Kaban-Pruzansky type III). These patients will appear later in the chapter.

Box 30-1 Terms Used Synonymously With Craniofacial Microsomia

- Hemifacial microsomia
- Goldenhar syndrome
- Oculoauriculovertebral spectrum
- Otomandibular dysostosis
- First and second branchial arch syndrome
- Auriculobranchiogenic dysplasia
- Facioauriculovertebral dysplasia
- Unilateral mandibulofacial dysplasia
- Facioauriculovertebral malformation complex

In most patients, the condition is unilateral; thus the term *hemifacial microsomia* is most commonly used. However, 15% to 30% of cases have bilateral involvement (bilateral HFM) and usually have differential involvement with asymmetrical hypoplasia.² Therefore the term *craniofacial microsomia* is more appropriate, and the two subtypes are distinguished as unilateral CFM and bilateral CFM. Although CFM is a more inclusive description and encompasses the wider spectrum of presentation, it fails to fully address the small subset of patients with associated extracranial anomalies. Clinicians and researchers are required to supplement the simplistic label with a fuller description that includes the affected components. An increasingly comprehensive classification schema has evolved.

EPIDEMIOLOGY

CFM is the second most common group of birth defects after cleft lip and palate, with an incidence of approximately 1 in 5500 live births. This incidence may be underestimated, however, with many of the milder forms of the condition potentially unrecognized.^{3,4} Some authors have suggested that isolated microtia should be considered a microform of HFM, which may further affect current incidence estimates.⁵

In a multicenter retrospective study, the odds ratio for developing CFM was 9 for multiple gestations (19 if infertility treatment was used), 6 if birth weight was less than 2000 g, and 5 if the family has a history of CFM, auricular abnormalities, or hearing loss.⁶ CFM was 40% more common in males and occurred more often on the right side. Low family income, low maternal weight (less than 18 kg/m²), discovery of pregnancy after 9 weeks, and previous termination or spontaneous abortion were each estimated to independently increase the risk of CFM. The risk of CFM was significantly lower for black mothers and was borderline increased for Native American mothers.

In a follow-up study, Werler et al⁷ examined first trimester exposure to vasoactive medications, including pseudoephedrine, phenylpropanolamine, aspirin, and ibuprofen. The authors found increased odds ratios associated with pseudoephedrine exposure, alcohol use, and the combined use of vasoactive medications and tobacco.

PATHOGENESIS

The underlying mechanism of CFM development is not fully understood but is thought to result from abnormal development of the first and second branchial arches. In normal development, the first branchial arch forms Meckel cartilage, which further develops into the mandible, muscles of mastication, most of the malleus, and the incus. The second branchial arch forms Reichert cartilage, which develops into the hyoid bone, styloid process, muscles of facial expression, and most of the stapes (Fig. 30-2).

In the most widely accepted theory of pathogenesis, a vascular insult impairs development of these first and second arch derivatives. Poswillo⁸ demonstrated features consistent with CFM in mice and monkeys by inducing hematomas in the region of the stapedia artery. The resultant tissue necrosis and variable regeneration are thought to explain the broad spectrum of features observed.

Retinoic acids produce anomalies in the axial skeleton, the craniofacial region, the cardiovascular system, and the central nervous system, similar to those seen in HFM.⁹

The discovery of a twin with microtia whose co-twin was resorbed in utero supports the hypothesis that some cases of HFM may be caused by the transfer of thromboplastin-rich blood from a dead to a living monozygotic or dizygotic twin through placental vascular channels.¹⁰

Fig. 30-2 Derivatives of the first, second, and third branchial arch cartilages.

GENETIC ASPECTS

Growing evidence supports a genetic basis for at least a proportion of HFM cases. Although most occurrences appear to be sporadic, a subgroup of patients have a family history of similar phenotypic characteristics. This subgroup was previously thought to be approximately 2% of HFM cases; however, more recent studies suggest that the incidence may be as high as 45%. This discrepancy may result from epigenetic mechanisms and/or variable expression, leading to under-recognition of mild phenotypic features in previous studies.^{4,11}

Studies examining familial HFM have shown a variety of inheritance patterns, including autosomal dominant and autosomal recessive.^{12,13} A variety of discrete chromosomal anomalies have been identified in patients with phenotypes consistent with the HFM spectrum. A chromosome 5p15 deletion, 12p13 deletion (*WNT5B* gene), partially overlapping microduplications on

14q23.1, anomalies on chromosomes 22q and 14q32 (*GOOSECOID* gene), and others have been implicated in the development of HFM.¹⁴⁻¹⁶

Despite these findings, the various gene defects have not yet been linked by a common molecular mechanism. The pathogenesis of HFM and its variants is probably as diverse as its phenotypic expression. Although Mendelian inheritance is possible in familial cases, sporadic cases may have multifactorial causes. This was shown by multiple studies demonstrating an increased incidence of HFM associated with maternal diabetes, smoking, twin pregnancies, and certain medications such as thalidomide and phenylephrine.¹⁶

Genetic counseling for families of children with HFM should include a discussion of the risk of sibling recurrence. In the absence of a family history and with a normal karyotype, this is approximately 2% to 3%.¹⁶ A thorough family history-taking is critical, because minor manifestations of the condition in relatives may have gone unrecognized and can potentially increase the risk of sibling recurrence.

THE CLINICAL SPECTRUM

Clinical features of CFM affect the various skeletal, muscular, neural, and soft tissue components to a varying extent¹⁷ (Table 30-1). A thorough physical examination with objective studies is essential given the wide spectrum of anatomic and corresponding functional abnormalities. A comprehensive evaluation involves multiple specialties, including genetics, plastic and craniofacial surgery, otolaryngology, audiology, anaplastology, speech and language pathology, psychology, ophthalmology, orthopedics, and dentistry (orthodontics and prosthodontics).

Table 30-1 Principle Craniofacial Anomalies of Craniofacial Microsomia

Facial Region	Abnormality	Incidence (%)
Mandible	Mandibular hypoplasia	89 to 100
	TMJ maldevelopment	24 to 27
Ear	Microtia	66 to 99
	Preauricular remnants	34 to 61
	Conductive hearing loss	50 to 66
Midfacial	Maxillary hypoplasia	
	Zygomatic hypoplasia	
Dental	Maldevelopment	
	Dental crowding	
Eye	Orbital dystopia	
	Microphthalmia	
	Epibulbar dermoids	
Mouth	Macrostomia	17 to 62
Muscle	Muscle hypoplasia	85 to 95
	Levator muscle hypoplasia	
Nerve	Cranial nerve VII palsy	
Soft tissue	Subcutaneous hypoplasia	

TMJ, Temporomandibular joint.

Skeletal Involvement

Although the extent of the deformity may include the entire hemicraniofacial skeleton, the mandibular deformity is considered the cornerstone (Fig. 30-3), and asymmetrical mandibular growth and development is the presenting complaint in most of patients. The posterior body of the mandible, the ascending ramus, the coronoid, and the condylar process have varying degrees of hypoplasia. The most severe cases have complete absence of the ramus and correspondingly the temporomandibular joint (condyle and glenoid complex). In such cases, the zygomatic arch may be absent and the temporal base hypoplastic.

The mandible plays a pivotal role in progressive distortion of the facial skeleton on the affected side, and secondary compensation occurs on the contralateral side. The natural history is progressive deviation toward the affected side, until the end-stage deformity is established at skeletal maturity. The normal downward vertical growth of the maxilla is restricted by the hypoplas-

Fig. 30-3 The variability in the skeletal deformity of CLP is shown in a series of CT scans. Common to all of the cases is a mandibular deformity with various components affected. **A**, Kaban-Pruzansky type I. **B**, Kaban-Pruzansky type IIA. **C**, Kaban-Pruzansky type IIB. **D**, Kaban-Pruzansky type III.

tic mandible, resulting in multiplanar deficiency of the hemimaxilla and obliquity of the occlusal plane (coronal roll, transverse yaw, and sagittal pitch). The zygomatic arch, with the glenoid fossa, may range from fully present to rudimentary to completely absent. The zygomaticoorbital complex is affected in up to 15% of patients, with varying degrees of inferior, medial, and rotational displacement of the orbit. Microphthalmia may be present. In more extensive cases, the involvement extends to the cranial vault (frontal bone) and skull base (temporal bone). Malformations of the cervical vertebrae can occur and include the presence of hemivertebrae and fused vertebrae.

In the cases of CFM with involvement of the orbit, cranium, and vertebrae (Fig. 30-4), clinicians should not focus solely on the mandibular asymmetry. Interventions should be performed within the context of the entire spectrum of involvement. Correction of the mandibular-maxillary relationship does not necessarily correct the upper midfacial involvement, and symmetry with respect to the absolute reference plane of the skull base must be clearly understood.

Fig. 30-4 The variability in the skeletal deformity of CFM is shown in a series of CT scans. With increasing severity, the maxilla, zygoma, orbit, and cranial vault are affected as part of the broad spectrum of presentation. **A**, Maxillary deficiency. **B**, Maxillary rotation. **C**, A hypoplastic zygoma with orbital dystopia. **D**, Microphthalmia. **E**, Hemivertebrae fusion.

Fig. 30-5 An ortho-Panorex radiograph shows the dental crowding and crossbite that accompany a hypoplastic mandible.

Dental Involvement

Skeletal hypoplasia, primarily of the mandible, results in dental crowding, crossbite, and deviation of the anterior teeth toward the hypoplastic side.¹⁸ Underdevelopment of the posterior mandibular body region correspondingly affects the posterior molar development, and in severe cases, the posterior dentition will be absent and require prosthodontic replacement (Fig. 30-5). In some cases the condition may also be associated with enamel defects and hypodontia, and patients may be at increased risk for early childhood caries.¹⁹

Muscular Involvement

The temporalis muscle normally inserts into the coronoid process, the lateral pterygoid muscle inserts into the condyle, and the medial pterygoid inserts into the mandibular angle. However, when the skeletal components of the mandible are diminutive or absent, then the corresponding muscle origins and insertions are affected (Fig. 30-6). When the zygomatic arch is absent, the origin of the masseter is affected, and in such cases the temporalis and masseter muscle may become confluent. Functionally, the chin deviates to the affected side with opening and closing. Thus symmetry achieved with skeletal reconstruction, including construction of a pseudotemporomandibular joint, is only a static symmetry and cannot restore normal symmetrical oromotor function. Lateral gnathism always occurs, except in the mildest forms of CFM. The muscular involvement extends intraorally, and in some cases, muscular hypoplasia of the levator palatini on the affected side and asymmetrical functioning result in velopharyngeal insufficiency.²⁰

Neural Involvement

The branches of the facial nerve can be involved to varying degrees. The marginal mandibular nerve is most often involved, resulting in lower lip asymmetry that is distinctly more noticeable with smiling (Fig. 30-7). The next most commonly involved branches are the temporal and zygomatic branches, affecting eyelid closure and placing patients at risk for exposure keratitis.

Fig. 30-6 A cross-sectional CT scan reveals the hypoplastic muscle that accompanies the skeletal deformity as it affects the normal origin and insertion. Absence of the zygomatic arch would affect the masseter muscle. Absence of the coronoid would affect the temporalis muscle. Absence of a condyle would affect the lateral pterygoid muscle, as shown in **A**, Pruzansky grade II and in **B**, Pruzansky grade III deformities. Absence of the coronoid would affect the temporalis muscle. (*, Affected side; LP, lateral pterygoid muscle.)

Fig. 30-7 This patient has involvement of the marginal mandibular nerve on the left side with resulting asymmetrical lower lip muscular function.

Auricular Involvement

Auricular involvement ranges from the presence of preauricular tags to complete absence of the external ear (anotia) (Fig. 30-8). Within these extremes, microtia is seen in 66% to 99% of patients with CFM and is usually associated with a 50- to 55-decibel hearing loss on the affected side.^{17,21} Atresia of the external auditory canal and middle ear abnormalities are frequent findings and are associated with varying degrees of conductive hearing loss. Less often, abnormalities of the in-

Fig. 30-8 CFM has a broad range of auricular involvement, from anotia to an unaffected ear. **A** and **B**, Lobular-type microtia. **C**, Anotia.

ner ear canal, cochlea, and semicircular canals occur and may lead to sensorineural hearing loss and/or balance disturbances.^{22,23} These malformations of inner ear structures are not explained by a defect of the first and second branchial arches, and additional pathogenic mechanisms such as failure of neural crest migration and a defect of blastogenesis have been proposed as contributing factors.^{24,25} The severity of external ear deformity has been shown to correlate closely with the degree of middle ear malformation, whereas temporal bone abnormalities are predicted by the severity of mandibular hypoplasia.^{26,27} Temporal bone CT is helpful in delineating the dysmorphology of the middle and inner ear structures, and grading the extent of abnormal anatomy (Jahrsdoerfer classification) can help to guide surgical planning.²⁸ In patients with unilateral CFM, hearing in the normal-appearing, contralateral ear is usually unaffected. However, a few patients have an associated conductive or mixed hearing loss on the contralateral side, thought to result from the presence of effusions and otitis media.²⁹ Identifying patients with bilateral hearing loss early is crucial, because early intervention is required to prevent problems with speech and language development. Every patient with atresia of the external ear canal should therefore undergo an early audiologic evaluation to determine the type and severity of hearing loss.

Ocular Involvement

Ocular findings are present in approximately two thirds of patients with CFM and are more common in patients with the Goldenhar syndrome variant³⁰ (Fig. 30-9). Epibulbar dermoids, a form of choristoma, are the most frequent finding and are usually seen in the inferotemporal location. Conjunctival lipodermoids (dermolipomata) are more yellow in color compared with epibulbar dermoids and arise superotemporally or inferiorly.³¹ Upper eyelid colobomas are seen in up to 24% of Goldenhar patients, most frequently at the junction of the middle and central thirds, and are usually quadrangular in shape.³² Colobomas require urgent attention, because failure to protect the globe can lead to corneal abrasion and subsequent scarring.

Fig. 30-9 Ocular findings in patients with CFM. **A**, An epibulbar dermoid. **B**, A lipodermoid.

Fig. 30-10 This patient has macrostomia (a Tessier number 7 cleft) as a component of CFM.

The function of the levator palpebrae muscle may be compromised in these patients, leading to congenital ptosis in 12% of patients with Goldenhar syndrome.³³ Additional ocular findings can include blepharophimosis, atresia of the nasolacrimal drainage system, strabismus, microphthalmia, and anophthalmia. The caruncles may be dysplastic, and colobomas can occur on the iris, optic nerve, and within the chorion or retina. These ocular features are usually unilateral but are bilateral in a small percentage of cases.³² An associated facial nerve palsy may lead to lagophthalmos, with the attendant risks of corneal drying and ulceration.

Lip Involvement

A lateral or transverse facial cleft (Tessier number 7) is present in approximately one quarter of patients with CFM and manifests as macrostomia (Fig. 30-10). This finding is five to six times more likely to be unilateral and is usually on the same side of the face as the other predominant features of CFM.³⁴ The severity ranges from mild widening of the oral aperture with loss of commissural anatomy to a full-thickness cleft running from the mouth to the tragus. The cleft may affect skin, subcutaneous fat, muscles of mastication, facial expression, and buccal continence. Severe cases

Table 30-2 Classification of Macrostomia

Type	Features*
I	Minor unilateral macrostomia
II	Major unilateral macrostomia
III	Minor bilateral macrostomia
IV	Major bilateral macrostomia

*The distinction between minor and major macrostomia is made when the cleft extends laterally to the anterior border of the masseter muscle.

can have underlying bony discontinuity. Labial clefting is also associated with greater severity of orbital involvement.³⁴ In a series of 12 patients with macrostomia, Gleizal et al³⁵ reported that the extent of muscular clefting can continue sagittally to include the tonsillar pillar or laterally to involve the masseter, and any repair must address these deficiencies. The authors proposed a surgical classification scheme that includes these features³⁵ (Table 30-2).

Cleft lip and palate deformity is reported in 10% of patients with CFM and, similar to patients with a Tessier number 7 cleft, occurs on the predominantly affected hemiface. The management of this deformity in patients with CFM is similar to that for patients with isolated cleft lip and palate and is described in Chapter 19. The presence of labial clefting, either in the form of a cleft lip or a lateral facial cleft, can lead to oral incompetence with attendant feeding difficulties, salivary incompetence, and later, speech problems, and warrants early correction.

Soft Tissue Involvement

Although much of the deformity involves the skeletal framework, skin and subcutaneous tissue are also involved with varying degrees of volumetric and corresponding skin surface area deficiency. The parotid gland is deficient in some patients. Restoring symmetry requires addressing the tissue “upholstery” of the skeletal framework.

Extracranial Involvement

Associated extracraniofacial anomalies can involve multiple organ systems, including the central nervous system, heart, skeleton, lungs, gastrointestinal tract, and kidneys. These are listed in Box 30-2.³⁶

OBJECTIVE STUDIES

Abnormal growth and development of the craniofacial structures and the impact of intervention must be properly documented to define the anatomic extent of the deformity and its functional effect. This is essential to optimize treatment planning and assess outcomes.

Standardized, two-dimensional digital photographs are needed to document not only the extent, but also the progression of facial deformity from infancy to adulthood. The recently published Phenotypic Assessment Tool for CFM provides an example of a standardized photographic

protocol³⁷ (Fig. 30-11). Although two-dimensional photographs are the minimum standard, the complex asymmetry of patients with CFM is best captured, documented, and analyzed with three-dimensional image-capture devices and photogrammetry (Fig. 30-12). When possible, such imaging should be performed annually and more frequently when rapid changes are occurring in early childhood development and with surgical intervention. Currently available CT scans with three-dimensional reconstruction are indispensable to surgeons for fully detailing the skeletal involvement, for defining the complex asymmetry in all three planes, and for surgical planning (Fig. 30-13). Moreover, they are the only objective tool for measuring the outcomes of surgical intervention.³⁸

Fig. 30-11 A standardized, two-dimensional photographic record as part of the Phenotypic Assessment Tool for patients with CFM.

Fig. 30-12 Images of a patient with CFM captured using a three-dimensional camera system (see the accompanying video). The digital data provide linear surface distance, surface areas, and volumes that can be measured.

Fig. 30-13 A three-dimensional craniofacial CT scan of a patient with CFM and asymmetry in all three planes.

CFM can be diagnosed based on clinical examination; however, the impact of the embryologic fault on the underlying structures cannot be fully assessed. In a recent review of 41 patients, Wink et al³⁹ demonstrated poor correlation between clinical scoring according to the Kaban-Pruzansky classification (see Table 30-3) and classification based on three-dimensional CT imaging. They questioned the reproducibility of the currently accepted method. We prefer to obtain a three-dimensional CT scan at the time of the initial evaluation to fully establish the extent of involvement and to guide overall treatment planning. At subsequent time points, we prefer to use the lower radiation dose of a cone-beam CT scan primarily for orthodontic intervention and a conventional, medical three-dimensional CT scan when high-resolution detail is needed that may affect surgical intervention. In most instances we can limit the radiation dosage without ultimately affecting outcome.

A number of functional studies are relevant to children with CFM. Annual audiograms are essential to maintain and monitor the hearing of the unaffected side. Testing is needed to assess the value of bone conduction hearing devices, which would be beneficial in many children with CFM to provide binaural hearing. Nasendoscopy is essential for assessing velopharyngeal function, and nasorhinometry is beneficial for evaluating the upper airway. Many children may have obstructive sleep apnea, and this is best documented by a formal sleep study. Neurodevelopmental and quality-of-life assessment tools, administered by psychologists, help to assess well-being.

CLASSIFICATION

The broad spectrum of phenotypic variability has led to a number of classification systems for CFM. Of the various skeletal classification schemes, the Pruzansky classification⁴⁰ of mandibular involvement, described in 1969, and its subsequent modification by Kaban et al⁴¹ in 1988 (Table 30-3) provide the most workable schemas for treatment planning. In Pruzansky grade I, all of the anatomic elements of the mandible are present, but they are of diminutive volume, compared with the unaffected side. In Pruzansky grade III, the ascending ramus, the coronoid process, the condyle, and the corresponding glenoid fossa are absent. The mandible tapers at what would be the angle in a normal mandible. Between these two extremes, all remaining hypoplastic mandibles (ramus, condyle, and coronoid process) are classified as Pruzansky grade II. The later modification by Kaban et al⁴¹ further subdivided Pruzansky grade II into type IIA, in which the glenoid fossa–condyle relationship is spatially maintained at the cranial base, and type IIB, in which the mandible and the corresponding glenoid fossa, if present, are displaced medially.

Table 30-3 Mandibular Classifications

Pruzansky Classification	Description	Illustration	Kaban-Pruzansky Classification
Grade I	Ramus, condyle, and glenoid are all distinctly present, but smaller compared to the unaffected side.		Type I
Grade II	Ramus, condyle, and coronoid are present each to a varying extent but are hypoplastic and abnormally shaped.		Type IIA
	Ramus, condyle, and coronoid are present each to a varying extent but are hypoplastic and abnormally shaped.		Type IIB
Grade III	Complete absence of ramus, glenoid fossa, and TMJ. The mandibular body length is also typically short on the affected side.		Type III

The Pruzansky classification⁴⁰ and the modification by Kaban et al,⁴¹ which describes two subtypes of Pruzansky grade II based on the temporomandibular joint morphology (*TMJ*) and position. These help to direct the surgical treatment and affect the outcome. Type IIA has a well-defined articulation that acts as a superior “stop” for mandibular distraction and conventional orthognathic surgery.

Table 30-4 Classification of Hemifacial Microsomia

Type	Description
Type IA	The craniofacial skeleton is only mildly hypoplastic, and the occlusal plane is normal.
Type IB	The craniofacial skeleton is as in type IA, but the occlusal plane is canted.
Type II	The condyle and part of the affected ramus are absent.
Type III	In addition to the findings in type II, the zygomatic arch and glenoid fossa are absent.
Type IV	This type is uncommon, with hypoplasia of the zygoma and medioposterior displacement of the lateral orbital wall.
Type V	This is the most extreme type, with inferior displacement of the orbit and a decrease in orbital volume.

The classification, although limited to the mandible, is helpful for managing lower skeletal asymmetry. Lauritzen et al⁴² proposed a schema that addressed the midfacial and orbital skeletal asymmetry that accompanies the mandibular deficiency (Table 30-4).

More inclusive systems include the Skeletal, Auricular, and (Soft) Tissue classification, and the Orbit, Mandible, Ear, Nerve, and Soft Tissue (OMENS) classification.^{3,43} The OMENS classification is the most widely used in practice and has undergone refinement to include extracranial anomalies (now called *OMENS-Plus*)⁴³ (Table 30-5) and pictorial representations of the various deformities^{36,37,44} (Fig. 30-14). Using the OMENS-Plus system, each extracranial anomaly is recorded by organ system and counted once; for example, OMENS + 2 cardiac (1 = atrial septal defect [ASD]; 2 = ventricular septal defect [VSD]). Gougoutas et al⁴⁴ presented a more recent pictorial classification of OMENS that provides an excellent visual tool. Compared with the more simplistic Pruzansky classification, the more comprehensive classifications are not as clinically practical in guiding the surgical treatment planning. However, they have the benefit of ensuring that all components of an anomaly are assessed and objectively noted for management.

Table 30-5 Orbit, Mandible, Ear, Nerve, and Soft Tissue Classification System

Side: Right or Left				
Orbit	Mandible	Ear	Facial Nerve*	Soft Tissue
The midsagittal plane is defined by a vertical line from the crista galli to the anterior nasal spine, and a horizontal line is then drawn at a right angle to the midsagittal plane tangent to the supraorbital rims. Orbital features are characterized as follows:	The mandible is evaluated radiologically and categorized as follows:	External ear anomalies are categorized based on a clinical examination and standardized photographs as follows:	Facial nerve weakness is categorized based on a clinical examination as follows:	Soft tissue anomalies are categorized based on subcutaneous and apparent muscular deficiency as follows:
O ₀ : Normal orbital size and position	M ₀ : Normal mandible	E ₀ : Normal ear	N ⁷ ₀ : No facial nerve involvement	S ₀ : No obvious soft tissue or muscle deficiency
O ₁ : Abnormal orbital size	M ₁ : Mandible and glenoid fossa are small with a short ramus	E ₁ : Mild hypoplasia and cupping with all structures present	N ⁷ ₁ : Upper facial nerve involvement (temporal and zygomatic branches)	S ₁ : Minimal subcutaneous/muscle deficiency
O ₂ : Abnormal orbital position (O ₂ ¹ for superior, O ₂ ¹ for inferior)	M ₂ : Mandibular ramus short and abnormally shaped Subdivisions A and B based on the relative positions of the condyle and TMJ 2 _A : Glenoid fossa in an anatomically acceptable position with reference to the opposite TMJ (based on submental vertex views) 2 _B : TMJ inferiorly, medially, and anteriorly displaced; mandible severely hypoplastic	E ₂ : Absence of external auditory canal with variable hypoplasia of the concha	N ⁷ ₂ : Lower facial nerve involvement (buccal, mandibular, and cervical branches)	S ₂ : Moderate; between the two extremes, S ₁ and S ₃
O ₃ : Abnormal orbital size and position	M ₃ : Complete absence of ramus, glenoid fossa, and TMJ	E ₃ : Malpositioned lobule with absent auricle; lobular remnant usually inferiorly and anteriorly displaced	N ⁷ ₃ : All branches of the facial nerve affected	S ₃ : Severe soft tissue deficiency as a result of subcutaneous and muscular hypoplasia

*Other involved nerves are signified by the appropriate number in superscript (for example, N⁵ [sensory] and N¹²).

MANAGEMENT OF CRANIOFACIAL MICROSOMIA

The treatment planning is individualized for every patient, given the wide spectrum of presentation. This includes not only the surgical and dental components, which are frequently emphasized, but also the needed hearing, speech, and psychological support. The intervention is ideally timed in conjunction with the growth and development of the child from infancy to adulthood. This often involves close coordination between the various interdisciplinary specialties. The speech pathologist and the plastic surgeon coordinate the need for velopharyngeal surgery. The audiologist, otolaryngologist, anaplastologist, and plastic surgeon coordinate the timing for external auricular reconstruction with placement of implants for bone conduction hearing and retention of the ear prosthesis if prosthetic rehabilitation is indicated. The plastic surgeon, orthodontist, and prosthodontist communicate to effectively plan dentoskeletal surgery. Microtia reconstruction is coordinated with the skeletal reconstruction and with soft tissue augmentation. The child and parents need to set aside time from school and work, which may be detrimentally affected by numerous appointments and surgical intervention. Thus the psychologist and the social worker are valuable members of the team, assisting families by providing support and ensuring well-coordinated care.

From a surgical perspective, broad principles and general rules guide the reconstructive sequence. The restoration of facial symmetry begins by establishing symmetry of the underlying dentoskeletal framework. Only then can soft tissue augmentation and auricular reconstruction be consistently successful. Positioning the ear appropriately with respect to the contralateral side is less likely to be satisfactory if the underlying skeletal symmetry is not established first. This fundamental principle is the ideal for patients presenting at end-stage skeletal maturity, but may need to be modified in selected cases. Many children will present in early childhood with such severe facial asymmetry that soft tissue augmentation in the form of a vascularized free flap may be required well before the child reaches skeletal maturity. Similarly, to assist children with hearing, a bone-anchored hearing device may need to be placed well before microtia reconstruction, which is dependent on the underlying skeletal symmetry. When determining the location of implant placement for a bone-anchored hearing device, surgeons need to consider future ear reconstructions; the device should not interfere with the position of later autologous or pros-

thetic reconstruction. Thus surgeons must adapt the reconstructive principles to meet the needs of each patient, the parents, and the task at hand. In many cases, the surgeon must anticipate the final form and view the reconstruction in components.

Component Facial Analysis

Patients who present with a craniofacial asymmetry require a systematic approach. Each of the components—skeletal, dental, and soft tissue—is assessed in all three anatomic planes in relationship to the other two (intrinsic spatial relationship) and in relationship to the external, three-dimensional space in which they are embedded. The natural head position (external reference frame) is noted. Knowing where the head is held in three-dimensional space is critical in understanding where to begin to establish the planes of symmetry (Fig. 30-15, *A*). Many patients with craniofacial asymmetry present with a head tilt because of ocular muscle imbalance, orbital dystopia, persistent muscular torticollis, or cervical spine abnormalities. For such patients, correction of asymmetry begins with a discussion with the patient in which the surgeon explains that the asymmetrical position of the head in three-dimensional space is to be distinguished from the internal asymmetry of the facial components. Together, they decide whether treatment will be planned with respect to the horizon, the level of the pupils, or an agreed-on external reference plane.

To determine the internal relationship of the facial components of symmetry, surgeons must establish the true facial midline, “mirror-image” plane of symmetry with which the reflection about the plane can be compared (Fig. 30-15, *B*). However, in many patients with craniofacial asymmetry involving the cranioorbital region, defining that plane can be difficult. Geometrically bisecting the interpupillary line is not always reliable. For example, in a patient with a severe craniofacial asymmetry that extends to the orbit and cranial base, the plane that bisects the interpupillary distance does not necessarily match that of a plane defined by the skull base (crista galli and sella turcica). Thus, with the more severe forms of craniofacial asymmetry, when the plane of symmetry is difficult to objectively define, clinicians should use their judgment to determine which elements can be surgically altered to an acceptable appearance.

Fig. 30-15 This patient has CFM. **A**, For this photograph, she was asked to look at the distant horizon. The horizon is used as an external reference plane from which the midsagittal plane can be defined. **B**, Internal reference planes based on the interpupillary line as the horizon. The surgeon needs to decide with the patient which line of symmetry to use, if the upper midface (orbit) is not repositioned as an initial procedure.

Reyneke et al⁴⁵ provided a simplified asymmetry classification based on the chin, mandible, and maxilla to guide orthodontic and surgical management. However, once the asymmetry includes the cranioorbital structures and extends to involve the soft tissue and facial elements, such as the ears, ocular adnexa, nose, and lips, each of the components of the face must be analyzed independently for spatial position and shape. A geometric object in three-dimensional space has six degrees of freedom that determine its spatial position: three translational (delta x, delta y, and delta z) and three rotational (roll, yaw, and pitch). The definition of the shape is more complex but is intuitively represented by volume and surface topography.

In a comprehensive analysis of asymmetry, the face is anatomically broken down into its geometric components: the skeletal masses, the dental arches, the soft tissue envelope, and the individual facial elements. Each of these components is defined by its spatial position in space relative to the reflection plane or plane of symmetry and by its individual shape relative to its counterpart (Fig. 30-16).

Fig. 30-16 A component analysis of facial asymmetry. **A-C**, The facial skeleton is assessed regionally based on each of the skeletal elements in terms of its three-dimensional spatial relationship to the facial midline axis and to its shape to the mirror-image counterpart. Osteotomies can be made and the elements repositioned. Autologous bone grafts are used to support the gaps. Distraction can be performed when bone is sufficient; however, vascularized free flaps are used for missing elements. Alloplastic implants may be required to restore the surface topography when repositioning the bone elements alone is not sufficient. **D-F**, This patient will require all available surgical options. The soft tissue envelope is assessed regionally, and autologous soft tissue augmentation is nearly always needed, despite restoration of symmetry to the skeletal framework. The auricular element and the macrostomia will need to be reconstructed.

The skeletal masses are the building blocks that structurally define the framework of the face. These include the frontal bone, the orbital complex, the malar-zygoma region, the maxilla, and the mandible. The mandible itself is a composite of the ramus, body, and symphysis. The dental midline, arch form, roll, yaw, and pitch of each maxillary and mandibular dental arch needs to be assessed independently. Each arch is then assessed with respect to its skeletal bases: the maxillary dental arch to the maxilla and the mandibular dental arch to the mandible. The relationship between dental arches is assessed. The thickness of the soft tissue envelope of the skeletal framework is evaluated in regional subunits, measured from the skeletal surface (volume deficiency or excess) and surface topography to achieve the desired symmetry, because correction of the un-

Fig. 30-17 Surgical options for skeletal and soft tissue reconstruction are tailored to the degree of severity for each component. The basic principles, regardless of the cause of asymmetry, include (1) establishing an axis of symmetry to correct roll, yaw, and pitch, (2) rearranging the existing skeleton through osteotomies and repositioning of each element, (3) including bone grafts, skeletal distraction, and microvascular bone transfer for restoration and skeletal stability, (4) refining with custom prosthetic implants to improve surface topography, (5) augmenting soft tissue through autologous grafts and microvascular tissue transfer, and (6) re-constructing missing elements such as the ear, eye, and lips.

derlying framework does not necessarily correct the soft tissue envelope. Finally, the individual facial elements that ultimately define the face are assessed for their spatial position and shape.

Thus, when a patient presents with asymmetry, every component must be carefully assessed. Only then can a systematic, multistage, reconstructive blueprint be developed. Surgeons must have within their armamentarium a large number of procedures to address each component of facial asymmetry: skeletal, soft tissue, and functional facial elements (Fig. 30-17).

Surgical Planning

Traditional surgical planning for facial skeletal and soft tissue surgery is based on clinical examination, two-dimensional photographs, lateral and frontal cephalometric radiographs, and facebow mounting of dental casts. This well-established approach has provided good results in many patients for a half century. However, the outcomes were inconsistent for patients presenting with complex facial asymmetries. The two-dimensional analyses in the orthogonal planes were difficult to integrate in surgical planning with confidence. Although the facebow transfer provides guidance, patients with CFM can have dystopic microtia resulting in auricular asymmetry. The facebow based on the ear position assumes upper facial symmetry to restore lower facial symmetry. With each step of two-dimensional planning for a three-dimensional problem—from cephalometric analysis to dental model surgery—the errors accumulated and the effects were incorporated into the occlusal splint fabrication.⁴⁶ The accuracy of the resultant occlusal splint was reduced to that of a “rough guide” only, with the final assessment of the planning based on intraoperative assessment that requires considerable judgment and experience.

Microtia reconstruction was similarly plagued with mirroring the shape and form of the normal contralateral ear and accurate positioning in three-dimensional space. Two-dimensional radiographs were used as templates. The normal ear was traced onto the film, and the templates were cut out and sterilized to be used in the operating room to construct an ear. Positioning of the ear reconstruction also involved a radiographic film. The normal ear was traced in relation to the brow, nose, and lip commissure. The reverse of the film provided the mirror image for positioning. Accuracy was difficult.

More contemporary approaches to this challenge can be performed digitally and preoperatively, allowing verification of positioning and symmetrical sizing before the actual surgery (Fig. 30-18). Two- and three-dimensional digital photography offers an efficient means of employing transparent two-dimensional replicas of the unaffected ear to position the planned reconstruction directly on the patient. However, the reconstructed visual symmetry of the pinnae may not be technically symmetrical; that is, the reconstructed ear is a mere mirror image of the unaffected ear (Fig. 30-19). In CFM patients, facial asymmetry in which horizontal lines through facial elements—eyebrows, canthi, base of the nose, and lip commissures—generally converge, indicates the need for a more intuitive approach to achieve visual symmetry rather than absolute symmetry (Fig. 30-20). An ear with absolute symmetry (that is, a mirror image) on a CFM patient with these characteristics would look far too large in comparison to the contralateral ear and would probably present challenges related to the position of the hairline. Many CFM patients have an inferiorly positioned hairline, which presents its own challenges in ear reconstruction. Perceived, visual symmetry is not absolute. Achieving the appearance of facial symmetry in these patients requires careful consideration.

Fig. 30-18 Planning techniques for autologous reconstruction. **A** and **B**, Conventional planning. **C**, Digital planning.

Fig. 30-19 Virtual surgical planning for accurate placement of osteointegrated implants, positioning the prosthetic ear in three-dimensional space using a mirror-image technique.

Fig. 30-20 Achieving symmetry in CFM patients is not an absolute science.

Using simple computer-based techniques and two- and three-dimensional digital photography, surgeons can make intuitive decisions toward a patient's treatment goals. An added benefit is the ability to reproduce the two- and three-dimensional photographic data into virtual planning models and surgical guides using conventional and three-dimensional printing for positioning, placement, and template shape and definition. Many of the same tools are available for planning more complex surgical interventions involving hard and soft tissues.

Currently, the software for virtual surgical planning is capable of simulating surgical procedures with ever-increasing user applicability, from the imaging research laboratory to routine daily clinical application.⁴⁷⁻⁴⁹ The facial skeleton is treated as a solid, three-dimensional object in virtual space that can be digitally manipulated. Osteotomy planes can be defined, and the three-dimensional facial skeletal object can be digitally sectioned into two separate solid objects, allowing each to be moved independent of the other. The software treats the CT data set as solid objects on which Boolean algebra can be performed. Three-dimensional visual objects can be added and subtracted digitally. Using the registration and superimposition technique, it is possible to build an integrated, composite model of the dentition, based on both volumetric information from CT or cone-beam CT and surface information from laser or optical scans with greater clinical accuracy. Surgery can be planned in three-dimensional space instead of in planar projection, two-dimensional cephalometric films. The complex facial skeletal asymmetries can be addressed. Moreover, the conventional inaccuracies and time-consuming laboratory process of facebow transfer, plaster mounting of dental casts, sectioning, repositioning, and remounting of dental casts are eliminated. Surgeons can execute various surgical options to optimize outcomes. Regions of interference during the skeletal movement can be assessed and detected (for example, in patients with maxillary impaction and mandibular rotation), the dental roots can be visualized within a skeletal framework for interdental osteotomies, and the course of the inferior alveolar nerve can be visualized for mandibular osteotomies. The mirroring function of the software provides a more accurate template for microtia reconstruction, compared with the conventional use of two-dimensional radiographic templates. The templates to construct an ear and the positioning can be three-dimensionally printed.

Component Reconstruction

The sequence of reconstruction (beginning with the skeletal framework, the overlying soft tissue, and followed by the various specialized components) is described in the following section. Each component is integrated either in parallel or sequentially with the child's growth and development, functional needs, psychosocial concerns, and aesthetic goals (see Table 30-6).

Reconstruction of the Skeletal Framework***Cranioorbital Reconstruction***

In a small percentage of patients with CFM who present with frontoorbital involvement, establishing symmetry of the lower facial region (maxillary-mandibular) is dependent on establishing upper facial symmetry. When the patient is in childhood or early adolescence, a decision is made with the patient and family whether to address orbital dystopia through transcranial "box" orbital osteotomies. Currently available three-dimensional surgical planning software is invaluable in assisting surgeons in positioning the orbit using the mirror-image function. The technical details of repositioning and orbital expansion osteotomies are well described in the literature.^{50,51}

Maxillary-Mandibular Dental Reconstruction

Established surgical principles involve complete disassembly and reassembly of the maxillofacial skeleton, carefully designed osteotomies, repositioning and fixation of the bony elements to their desired position, and rigid skeletal fixation systems supported by bone grafts.⁵² These classical procedures, the LeFort I osteotomy, bilateral sagittal split osteotomy, and genioplasty, are described in detail in Chapter 27. For patients with CFM, a classic LeFort I osteotomy pattern is modified to account for the asymmetry to achieve a desired result (Fig. 30-21). The osteotomy on the uninvolved side of the face may follow the classic downward-sloping osteotomy line through the maxilla, and on the deficient side, the osteotomy may be upward sloping to include a portion of the zygoma. The mandibular osteotomies will also be asymmetrical to achieve a more symmetrical outcome. For patients who have a relative degree of symmetry, surgeons need only address the rotation of the maxillary-mandibular complex in the sagittal plane to achieve a proper pitch or occlusal cant. The complexity with CFM patients involves a rotational element not only in the sagittal plane but also in the coronal plane (roll or cant) and the transverse plane (yaw). Therefore repositioning with six degrees of freedom adds a significant level of complexity to obtain the desired outcome. Moreover, the desired asymmetry has anatomic limitations. The impact of mandibular rotation on the condyle within the glenoid fossa can be significant. Surgeons should be concerned about internal derangement of TMJ function. The mandibular shape itself is abnormal, and achieving symmetry is limited through osteotomies and repositioning alone.

These procedures are performed presuming bony material is sufficient to rearrange the skeletal framework to achieve the surgical goals, but this is rarely the case in CFM patients. The exception to this rule is in Pruzansky grade I patients, in whom asymmetry is minimal, although clinically evident. If skeletal stability is a concern because of the amount of desired advancement (bone length) and excessive soft tissue and muscular forces contributing to relapse, skeletal distraction is added to the surgeon's armamentarium. Classic orthognathic procedures and distraction osteogenesis procedures use the same osteotomy pattern; the fundamental difference is the rate of displacement of the bone segments. With classic orthognathic procedures, the immediate final position of the bone segment is subject to strong relapsing forces and needs to be supported by skeletal fixation and bone grafting of the osteotomy gap. With distraction osteogenesis, the slow rate of displacement in the range of 1.0 mm/day allows gradual accommodation of the soft tissue and muscle matrix in which the skeletal framework is embedded. The biologic principles and the clinical application have been well described since its introduction in 1990.⁵³⁻⁵⁵ Distrac-

Fig. 30-21 Virtual surgical planning of orthognathic surgery (model surgery). **A**, An asymmetrical LeFort I osteotomy tailored to a patient's deformity with the cant (roll). **B**, Yaw correction after a double-jaw surgery and assessment of interference at the bilateral sagittal splitting osteotomy junction. **C**, Sagittal correction with dynamic cephalometric analysis. **D**, An intermediate position with maxillary surgery first and design of the intermediate splint to be fabricated for intraoperative positioning of the maxilla relative to the mandible (see the accompanying video).

tion osteogenesis is an important surgical tool in mandibles classified as Pruzansky grade II, in which bone stock is insufficient for the classic orthognathic procedures but sufficient for distraction. With mandibular distraction alone, an open bite is created on the involved side, allowing the maxilla to be leveled with orthodontic appliances (Fig. 30-22). With simultaneous maxillary distraction driven by mandibular distraction, both jaws can be leveled to the extent limited only by the vector control of the distraction device (Fig. 30-23). In severe cases, the desired symmetry may be difficult to obtain through distraction alone, particularly when multiple vectors for lengthening are required. In these cases, the goals of distraction may be to achieve satisfactory maxillary position and sufficient mandibular length to facilitate a classic orthognathic procedure as a secondary procedure, offering surgeons more control in achieving symmetry (Fig. 30-24).

Fig. 30-22 This patient had left Kaban-Pruzansky type IIA CFM. Distraction osteogenesis was performed for mandibular lengthening with an external device. **A** and **B**, Before the distraction. **C**, During mandibular distraction osteogenesis. **D** and **E**, The postoperative result.

Fig. 30-23 A and B, Management of an occlusal open bite after left mandibular lengthening. C, After distraction, the resultant crossbite was evident. D, Orthodontic management. E, The contralateral right crossbite could have been corrected with a simultaneous palatal expansion. This occurs because of the inability to fully control the multivector direction with a single-vector distraction device.

Fig. 30-24 This patient had right CFM (Kaban-Pruzansky type IIB). A-F, Preoperative clinical images and CT scans showed the underlying skeletal anatomy.

Continued

Fig. 30-24, cont'd G-L, Surgical simulation of simultaneous maxillary and mandibular distraction. The virtual simulation offered surgeons an opportunity to optimize the vector of distraction. However, the true kinematics of the right temporomandibular joint could not be reproduced. M-O, The outcome at 8 weeks. The internal device was maintained until consolidation.

Distraction osteogenesis offers the benefit of harnessing patients' normal growth and development with earlier intervention. In patients with CFM, the benefits of an earlier mandibular distraction-lengthening procedure include improvements in the airway by repositioning the tongue base and lessening the secondary impact on the midfacial skeleton by removing the anatomic restriction of the mandible.⁵⁶ Nevertheless, surgeons should inform patients and their parents that, after these early interventions, further mandibular lengthening will be needed later in childhood, supported by orthodontic management, and conventional orthognathic surgery will be required in adolescence. There is a definite role for early, interceptive orthodontics, combined when needed with surgery, which can reduce the degree of asymmetry until more definitive skeletal procedures can be performed at maturity.

When bone is insufficient for distraction (for example, a Pruzansky grade III mandible), then the alternatives are nonvascularized bone grafts (costochondral rib grafts or iliac bone grafts) and vascularized bone transfer (fibula, scapula, or radius) through microsurgery techniques^{57,58} (Fig. 30-25). Once sufficient bone stock is present (that is, a Pruzansky grade III mandible is converted to a Pruzansky grade II mandible), distraction osteogenesis and classic orthognathic procedures can be completed to reduce the skeletal asymmetry.

Fig. 30-25 This patient with right CFM (Pruzansky grade III) underwent an asymmetrical LeFort I osteotomy, a left sagittal split osteotomy of the ramus, and a right rib graft and fibular reconstruction. **A-C**, Preoperative views showed occlusal cant and right-sided maxillary and mandibular deficiency. **D**, A fibula and rib graft for right mandibular reconstruction. **E**, A three-dimensional CT scan demonstrated the right-sided deficiency. **F** and **G**, Postoperative views show improved symmetry and correction of the occlusal plane. **H** and **I**, The reconstruction included asymmetrical osteotomies and graft placement.

Even with carefully tailored osteotomies and repositioning of the existing skeletal framework, residual asymmetry can result because of the abnormal shape of the bony contours of the mandible and the maxilla (Fig. 30-26). Skeletal contouring procedures are important to achieve the final symmetry. Autologous bone grafts and custom-designed, mirror-image alloplastic implants are required to restore the shape or the surface topography of the involved skeletal element, primarily the mandibular border and the maxillary-zygoma region.⁴⁹

Fig. 30-26 This patient had left CFM after a LeFort I osteotomy and a bilateral sagittal splitting osteotomy. **A**, A worm's-eye view showed residual midface asymmetry. **B**, A three-dimensional CT scan revealed residual zygomatic deficiency. **C** and **D**, Three-dimensional CT planning for correction of bony asymmetry with an alloplastic implant. **E**, Intraoperative placement of a porous polyethylene implant. **F**, The postoperative result.

Soft Tissue Reconstruction

Once the skeletal form is addressed, then soft tissue asymmetry of the overlying skin envelope can be corrected through a microsurgical vascularized adipofascial tissue transfer, nonvascularized dermal fat grafting, and structural fat grafting. When a large volume is required, a microvascular tissue transfer provides a good solution for patients with severe deficiency.⁵⁹ The choices include scapula, parascapula, anterolateral thigh, and deep inferior epigastric perforator flaps. However, tailoring the augmentation to specific facial regions is difficult, and many will require subsequent debulking and refinement procedures. Moreover, the appearance of the donor site needs to be carefully discussed. In many patients whose soft tissue deficiency is mild to moderate, nonvascularized dermal fat grafting is an appropriate choice. Some degree of volumetric resorption almost always occurs with nonvascularized grafts; therefore the augmentation is overcorrected generally by 20% to 25%, and some will require additional grafting. In recent years the introduction of serial, staged structural fat grafting has revolutionized the soft tissue asymmetry management in many patients. Fat is harvested from the abdominal and flank regions, purified, and infiltrated in small aliquots (0.1 cc) in a highly controlled manner in multiple planes, offering the surgeon a degree of precision that cannot be achieved by other approaches. As with dermal fat grafting, some resorption is inevitable, and structural fat grafting is generally repeated until the desired level of symmetry is achieved.⁶⁰⁻⁶²

Auricular Reconstruction

For severe microtia or anotia requiring total ear reconstruction with autologous cartilage, it is preferable to wait until patients are 10 years of age.⁶³ This ensures adequate costochondral cartilage is available and minimizes the resultant contour deficit at the chest donor site. Chapter 31 provides a more complete discussion of autologous total ear reconstruction. CFM patients present a number of unique challenges involving surgical planning, positioning of the reconstruction, and skin coverage. These issues are presented here.

Auricular Dystopia

With increasing severity of CFM, deficiencies of the underlying facial and cranial base skeleton can result in anterior, inferior, and medial displacement of the microtic vestige. The reconstructive plan for this displacement, known as *auricular dystopia*, should include restoration of a normal ear *position* and normal ear *form*. In patients with significant displacement, this may necessitate repositioning the dystopic vestige as a separate, preliminary operation before placing the auricular cartilage framework to maximize its blood supply for further movement at the later operation. The dystopic vestige is usually repositioned by Z-plasty, although it may also be transposed posteriorly on the leading edge of a cheek flap or as an island flap. This repositioning allows placement of the vestige closer to its ultimate position and increases the distance between the ear and the lateral canthus, both of which contribute to a less conspicuous deformity. This can be performed in early childhood, several years before the main reconstruction, without adverse effects⁶⁴ (Fig. 30-27).

In a few patients, the dystopic vestige can be associated with a patent external auditory meatus and canal. These structures and the adjacent facial nerve may limit the amount of available movement. The cartilaginous canal can be dissected sufficiently to allow pivoting around its connection with the bony canal, but the two segments must be kept in continuity. The superficial temporal and postauricular arteries should be preserved for future fascial flap transpositions. Preoperative imaging with CT or MRI can be helpful in determining the course of the canal, facial nerve, and vessels.

Fig. 30-27 This patient underwent transposition of a dystopic vestige. **A** and **B**, Preoperative views of the dystopic lobular remnant. **C**, Transposition of the dystopic remnant by a Z-plasty technique. **D**, The final result shows excellent symmetry.

Skeletal Hypoplasia

CFM patients with a hypoplastic temporal bone or cranial base may present an inadequate foundation for the ear, and reconstructive efforts that do not account for this are unlikely to be successful. The reconstructed auricle may be of appropriate shape and positioned appropriately in the transverse and coronal planes, but inadequate bony support leads to a reconstructed ear that remains *medially* displaced, particularly at the lower pole. The result is an ear that appears to have been sheared off the side of the head (Fig. 30-28, *A* and *B*). To address this, it is necessary to provide additional support for the cartilage framework when it is placed. In patients with mild skeletal hypoplasia, an additional block of cartilage can be placed under the main construct to provide the necessary projection, whereas in severe cases, a cantilevered cranial bone graft from the temporal bone may be necessary^{64,65} (Fig. 30-28, *D* and *E*).

Fig. 30-28 This patient had temporal bone hypoplasia associated with CFM. **A** and **B**, His ear was normal but malpositioned because of an underlying skeletal deficiency. **C**, CT reconstruction revealed a steeper angle of the temporal bone related to the craniofacial hypoplasia. **D**, Intraoperative exposure for cantilever bone graft placement. The external auditory canal was identified, and dissection was carried circumferentially to the level of the temporal bone. **E**, A cantilever bone graft and an additional bone strut. **F**, The arrangement of the grafts on the temporal bone. **G**, Grafts were secured to the temporal bone, encircling the canal. **H**, An early postoperative view, before mandibular reconstruction and ptosis repair. **I**, The final result.

Skin Coverage

Surgeons should be aware of the ultimate position of the ear when planning reconstruction. Many patients with CFM have a low hairline on the affected side. If the construct will require placement under mostly hair-bearing skin, then it may be more prudent to use a fascial flap with a skin graft to provide hair-free skin coverage in these cases (Fig. 30-29). Similarly, scarring from previous attempts at ear reconstruction, mandibular distraction, or bone-anchored hearing aid (BAHA) placement can potentially preclude placement of the construct under a healthy skin envelope, and instead necessitate the use of a fascial flap with a skin graft.^{66,67} For this reason, when possible, these earlier interventions are planned with the auricular reconstruction in mind, and placement of the incisions is adjusted accordingly.

Fig. 30-29 Auricular reconstruction with rib cartilage, a temporoparietal fascial flap, and skin graft coverage. The use of a fascial flap and skin graft was preferred in this case. The patient's low hairline would have resulted in hair-bearing skin covering a large portion of the reconstructed ear. **A**, A preoperative view showed right microtia with an anteroinferiorly displaced vestige. **B** and **C**, A clear template from the contralateral side helped to determine the correct position for the reconstructed ear. **D**, Operative markings confirmed the low-set hairline. Approximately half of the reconstructed ear would be placed under hair-bearing skin. The dystopic vestige was also repositioned at this stage.

Fig. 30-29, cont'd E, Harvest of a pedicled temporoparietal fascial flap, over which a skin graft can be placed. The superficial temporal artery is isolated. F, Placement of the rib cartilage framework. In this case, an additional cartilage block was placed behind the framework to compensate for the temporal bone deficiency. G and H, The auricular framework was positioned and covered with a full-thickness skin graft. I, The completed reconstruction.

Alloplastic Reconstruction

Alloplastic auricular reconstruction is an alternative to autologous reconstruction that involves placing a biocompatible porous polyethylene implant (Medpor, Stryker) under a vascularized temporoparietal fascial flap. The flap is covered with an anteriorly based skin flap and skin graft. Reinisch and Lewin⁶⁸ pioneered the technique. It provides a secondary option for patients who do not desire, or are not suitable candidates for, autologous reconstruction. The reported benefits include a shorter procedure with no donor-site pain or morbidity, single-stage reconstruction, and performing the reconstruction before patients enter school. With the use of custom implants, surgeons can better mimic the intricate features of the contralateral ear. However, the technique has disadvantages similar to those of other implant-based procedures, including infection and implant extrusion. Any exposure or threatened extrusion of the implant necessitates another operation, because the presence of a foreign body impedes healing of the overlying tissue. Salvage procedures are difficult. Although the rate of reported implant fracture is as high as 5% in patients undergoing atresia repair, the long-term failure rate is higher, as with any foreign body placement, and is unpredictable.^{68,69}

Auricular Prosthesis

Auricular prostheses can be custom fabricated to match a patient's contralateral ear and may provide the most symmetrical result, compared with all other reconstructive options (Fig. 30-30). The indications for auricular prosthesis in CFM patients include patient preference, poor operative candidates, salvage of an unsuccessful autologous reconstruction, and severely compromised tissue.⁷⁰ The benefits of prosthetic reconstruction over other means of reconstruction include minimal morbidity, excellent aesthetic results, and the ability to salvage with other types of reconstruction. The disadvantages include not using patients' own tissue, possible social embarrassment if the prosthesis becomes dislodged, and the need for regular replacement, which involves added expense and requires access to an appropriate provider.⁷¹ Table 30-6 provides a review of component reconstruction.

Fig. 30-30 This patient had right microtia and elected to have osteointegrated prosthetic ear reconstruction with simultaneous placement of a BAHA. **A**, Right anotia. **B**, A bar-and-clip retention device, anchored with osteointegrated titanium screws. **C** and **D**, Postoperatively, the right auricular prosthesis has excellent symmetry with the contralateral ear. **E**, The auricular prosthesis.

Table 30-6 Component Reconstruction

Age	Dentoskeleton	Speech	Ear	Mouth	Soft Tissue	Nerve
Infancy	Type II: Mandibular distraction Type III: Rib graft		Removal of preauricular remnants Lobule transposition	Macrostomia repair		
Early childhood		VPI surgery				
Late childhood	Type II: Mandibular distraction with orthodontic support Type III: Rib graft/vascularized fibula Growth modification phase I orthodontic management		Bone-anchored hearing aid		Dermal fat grafting Vascularized soft tissue flap Autologous fat grafting	Facial nerve reanimation Gold weight Lower lip botulinum toxin and myectomy
Early adolescence			Staged autologous microtia reconstruction			
Late adolescence to adulthood	Comprehensive phase II orthodontic management Type I: LeFort I, BSSO versus inverted L, genioplasty Type II: Simultaneous maxillary-mandibular distraction Type III: Rib graft/vascularized fibula Implant-retained dental prosthesis		Prosthetic ear reconstruction (failed microtia)			

Reconstruction must be tailored to each patient's needs and the staging of various components optimized for anatomic and functional benefit. *BSSO*, Bilateral sagittal split osteotomy; *VPI*, velopharyngeal insufficiency.

The prosthesis is made of silicone, and is color matched to the patient's skin for the best possible result (Fig. 30-31). The prosthesis is attached using a skin adhesive or by surgical placement of osteointegrated titanium screws into the temporal bone. With successful osteointegration, component retention systems can be designed using a bar-and-clip design or magnet retention. The benefits of osteointegrated implants include more reliable retention, ease of positioning and placement, and a longer expected lifespan of the prosthesis. Disadvantages of prosthetic reconstruction include the requirement for one or two surgeries for implant placement and abutment connection, respectively; design challenges associated with placing implants in inadequate bone where skeletal anatomy may be anomalous; aging of the silicone, as noted by discoloration and tearing of the prosthesis; and the patient's required commitment to daily hygiene maintenance of the periabutment tissue and prosthesis⁷² (Table 30-7). Prosthetic devices are custom made

Fig. 30-31 Extrusion of an alloplastic implant of a previously reconstructed ear can be corrected with surgical placement of implants to retain a prosthetic ear that is custom designed and color matched to the patient's skin. **A**, This patient had an extruding implant. **B**, Osteointegrated screws were placed with a bar-and-clip retention device. **C**, An auricular prosthesis is attached.

Table 30-7 Comparison of Autologous Versus Prosthetic Ear Reconstruction

Autologous Reconstruction	Prosthetic Reconstruction
Two surgical procedures	One or two surgical procedures
Technique-sensitive surgery	Less complex surgery
Longer initial healing time	Daily maintenance care of abutments
Lifetime maintenance free	Lifetime care of prosthesis
Uses a patient's own tissue	Lifetime maintenance and patient follow-up
Natural skin color match	Control of sculptural form
Limited control of form with the patient's tissue	Aging of artificial materials

for each patient, and therefore generally require multiple, sometimes lengthy, appointments for the initial design, fabrication, and fitting. Contemporary, computer-based approaches such as three-dimensional imaging, three-dimensional printing, and computerized color formulation have contributed to decreased treatment times, with improved accuracy, efficiency, and repeatability in the design, fabrication, and remake processes.⁷³ Given the relatively short lifespan of silicone prosthetic devices, access to a skilled practitioner who can reliably provide replacement prostheses over the span of a patient's lifetime should be considered.⁷⁴

The surgical technique for prosthetic rehabilitation involves implantation through an incision posterior to the external auditory meatus. Careful preoperative planning is essential to ensure appropriate placement of implants for the planned auricular restoration. Computer-based virtual surgical planning tools have become a trademark technique for many clinical teams who regularly perform these procedures and have access to the appropriate technologies. This becomes particularly beneficial when the availability, quantity, quality, and morphology of bone are unreli-

Fig. 30-32 Computer-based virtual surgical planning tools become essential when skeletal anatomy may be anomalous, particularly in CFM patients.

able, particularly in CFM patients (Fig. 30-32). Generally, in children, a two-staged procedure is preferred. In the first surgery, implants are placed in the bone and covered, and the skin is closed to allow osteointegration to occur. Three to four months later, the implant is uncovered and the percutaneous abutment is attached. After the skin heals (approximately 4 to 6 weeks), fabrication of the prosthesis begins. Healing times, based on the surgeon's assessment of bone quality during surgery, may vary with each patient. With abutment connection, revision of the subcutaneous tissue is required to achieve flat, tight adhesion of the skin to the bone during healing. This is essential to minimize adverse skin reactions of the periaabutment tissue and to facilitate the patient's ability to perform regular home hygiene to maintain tissue health.

Classifications have been defined to manage skin response of the periaabutment tissue.⁷² Auricular remnants, as in cases of microtia or failed reconstruction, can be excised at either the first or second surgery based on the surgeon's preference. Implant success is highest in uncompromised temporal bone. More implant failures are reported in the orbital bone and maxilla, sites common for retention of nasal and orbital prostheses. Implant failure is higher in irradiated bone. Where implant failure is a concern, additional implants are often placed as "sleeper" implants.⁷⁵ When implants are placed to retain an ear prosthesis and bone conduction device in the same surgical procedure, careful planning with an anaplastologist and audiologist is essential to ensure appropriate placement and adequate distance between implants.

Management of Hearing Loss in Patients With Craniofacial Microtia

Restoration of binaural hearing in patients with unilateral atresia has been shown to result in improved sound localization, distance hearing, and hearing in noisy environments and may be accomplished in a variety of ways.⁷⁶ Bone conduction hearing devices convert sound to vibration and are held against the scalp over the mastoid by a headband or metal spring clip. The disadvantages of these devices include high visibility and problems with skin irritation and breakdown from pressure.

Semiimplantable bone conduction devices (BCDs) are available. These can be direct-drive devices that transmit sound vibrations directly to the mastoid through an implanted percutaneous interface (Baha, Cochlear) or skin-drive devices, which are retained by an implanted magnet and transmit sound vibrations across intact skin. Direct-drive devices provide the most effective sound amplification; however, the percutaneous abutment requires daily care and may lead to problems such as skin irritation, overgrowth, and infection. Improved sound processing in the latest generation of skin-drive devices such as the Baha 4 Attract (Cochlear Bone Anchored Solutions) has made these a viable option for many patients.^{77,78}

Other options include transcutaneous direct-drive BCDs, such as the Bonebridge (MED-EL), which uses an implanted sound transducer and transmits only an electromagnetic signal across the skin. Preliminary results have been promising for this system.⁷⁷ Alternatively, a prosthesis (Vibrant SoundBridge, MED-EL) may be implanted in the middle ear, attached to either the stapes or oval window to stimulate only the ipsilateral ear and to potentially improve sound localization.⁷⁹ Canalplasty, or reconstruction of the external auditory meatus, canal, and tympanic membrane, can be attempted; however, this procedure requires a functioning middle ear and is associated with high complication and reoperation rates, and approximately 30% of patients will require a hearing aid postoperatively.⁷⁶

Macrostomia Reconstruction

Macrostomia is typically reconstructed in infancy to restore lip competence for oral feeding. The distance from midline to the unaffected oral commissure is used as a reference for the location of the reconstructed commissure. In bilateral cases, the demarcation between normal tissue and hypoplastic cleft tissue may be used instead. The commissure is reconstructed with triangular mucosal flaps, approximation of the oral and buccal musculature, and skin closure with a W-plasty.⁸⁰

Epibulbar Dermoid Cysts and Lipodermoids

The indications for removal of epibulbar dermoids and conjunctival lipodermoids are similar. Although these lesions are benign, they may pose a risk for visual obstruction with resultant amblyopia. Smaller cysts can be relatively inconspicuous; however, larger lesions may produce visible distortion of the iris and surrounding tissues, leading to obvious deformity. Children with epibulbar dermoids and lipodermoids should be referred to an experienced ophthalmologist for possible excision, which in many cases can be accomplished with minimal corneal scarring.⁸¹

Velopharyngeal Insufficiency

Palatal muscle hypoplasia may be present and can lead to velopharyngeal insufficiency in patients with CFM. In a series of 18 patients, Luce et al²⁰ reported significant velopharyngeal insufficiency in one third. The affected patients tended to be those with more severe hypoplasia of the maxillary-malar complex. Nasendoscopy and periodic speech evaluation should be used to

guide management, and surgical options are similar to those in the non-CFM population. However, the risk of obstructive sleep apnea in the presence of micrognathia should be considered.²⁰

Facial Nerve

Managing facial nerve palsy in patients with CFM is dependent on the pattern and severity of dysfunction, as with non-CFM patients. A complete discussion of facial nerve palsy and its management is provided in Chapter 38. However, in patients with hemifacial hypoplasia and concomitant facial nerve palsy, a free neurotized muscle-flap transfer, such as the gracilis or latissimus dorsi, can serve two purposes: restoration of dynamic facial animation and augmentation of tissue volume on the affected side.^{82,83} These techniques may be carried out in a single stage or as a two-stage procedure in combination with cross-facial nerve grafting and is an excellent option in these patients.

For patients with marginal mandibular nerve weakness, asymmetrical lower lip depressor muscle function can be mitigated by injection of botulinum toxin or by a surgical myectomy. The benefits of botulinum toxin injection are its convenience and minimally invasive nature; however, its effects are temporary, and repeated injections are required. Conversely, a myectomy can be a more permanent solution, but, even after this treatment, a small proportion of patients may require subsequent botulinum toxin injections for optimal efficacy.⁸⁴ Both techniques can be effective, and the choice should be tailored to the patient.

CONCLUSION

Restoring facial symmetry is one of the most challenging of all reconstructive procedures. Its difficulty lies in the extent of the involvement, ranging from purely skeletal asymmetry to involvement of all components of the facial structures. Restoring facial symmetry requires establishing an axis of symmetry, which becomes increasingly difficult with increasing severity of involvement. Although the craniofacial skeleton can be disassembled from the sphenoid and sectioned into its anatomic units, the challenge is in knowing where to position each of its bony elements relative to the facial axis and subsequently addressing the soft tissue surface and volumetric asymmetry. Today, surgeons, orthodontists, and anaplastologists have the benefit of viewing the three-dimensional asymmetry at multiple levels with cone-beam CT and three-dimensional surface cameras. These allow more accurate visualization of the morphologic deformity and planning of the surgical approach.

No other type of patient requires the same degree of imagination, innovation, and patience on the part of the surgeon and treatment team. Nearly every anatomic component can be affected by CFM. Similarly, challenges for patients and their families are equally difficult. From birth to early adulthood, and sometimes later, a child's habilitation can require numerous procedures, and a significant financial and time commitment on the part of the family. Many patients and their parents become tired, frustrated, and at times, uncooperative. Treatment should be planned with definitive goals in mind and conducted within a definite time frame so that these young patients do not think that their treatment is going on forever, with no end in sight. The orthodontist must accomplish as much as possible within a year in a first phase of treatment, not allowing a first phase to "melt" unnoticed into a second phase and subsequent orthodontic phases. Patients will notice, and the result may be a precipitous drop in rapport and cooperation as they become more frustrated and disheartened. Similarly, surgeons must have definite goals and carefully determine the number and timing of surgical interventions. Ultimately, success requires close working relationships between not only the surgeon and orthodontist, but also among the other members of

a supportive, multidisciplinary team, including psychologists, speech and language pathologists, prosthodontists, and anaplastologists. Paramount to any technically perfect, reconstructed face is the careful management of the patient's, parents', and family's expectations of treatment outcomes and the treatment experience itself. The most perfectly planned and executed treatment and symmetrically reconstructed face can be easily "dismantled" by unrealistic expectations of treatment. Honest, comprehensive, and compassionate education sets the foundation for successful treatment outcomes and a patient's physical, functional, and psychosocial rehabilitation.

KEY POINTS

- The spectrum of skeletal and soft tissue deformities seen in CFM arises when the normal developmental processes in the first and second branchial arches are disrupted.
- Many view microtia as a microform of the syndrome. Meticulous inspection will continue to reveal minor skeletal and soft tissue deformities of other branchial arch derivatives.
- Many classifications have been proposed based on either a single aspect of CFM (for example, the mandible, as in Pruzansky's classification) or the full spectrum of affected tissues (for example, OMENS-Plus). Some may prove more useful than others in treatment planning. The choice of classification system should be contextually based.
- Radiologic studies are necessary to fully define the anatomic deformity. CT with three-dimensional reconstruction offers refinement in anatomic and morphologic mapping to aid in the diagnosis, treatment planning, and post-surgical management.
- For comprehensive evaluation and management, these children should be seen regularly by a comprehensive craniofacial team.
- Airway and feeding are the two primary issues prompting early intervention. The role of distraction osteogenesis of the mandible in early decannulation and/or prevention of a tracheostomy is well documented.
- Upper airway compromise resulting from severe mandibular micrognathia in bilateral HFM may require consideration of bilateral mandibular distraction or the need for a tracheostomy.
- Macrostomia, because of an absence of the normal checkrein effect of the orbicularis muscle on oral competence, may result in failure to thrive. Early repair can significantly improve feeding.
- Children who are born with complete absence of the ramus, condyle, and temporomandibular joint fossa need reconstruction early in life.

- Delaying microtia reconstruction until patients are 10 years of age or older may allow better positioning of the reconstruction, particularly in cases of more severe deformity, when prior distraction or other skeletal reconstruction may have at least partially improved the symmetry of the underlying facial skeleton.
- In general, the success of soft tissue reconstruction depends on prior correction of the skeletal deformity. However, the treatment plan for each patient must be individualized, and patients with severe deformities may require soft tissue interventions well before the completion of skeletal growth.
- Modern imaging techniques, three-dimensional software reconstruction and Virtual Surgical Planning have eliminated much of the accumulated error associated with two-dimensional tracings and traditional model surgery, allowing more precision in complex movements of the mandible and maxilla.
- Patients and parents must understand that mirror-image symmetry cannot be achieved. Muscles that are not present cannot be created. A degree of asymmetry should always be expected.

Microtia

Gordon H. Wilkes • Regan Guilfoyle

Reconstruction of microtia has always been a challenge. Early attempts were largely unsuccessful. A myriad of techniques and materials have been used with limited long-term success. Radford Tanzer's landmark publications in 1959¹ started a new era in microtia reconstruction. Burton Brent's contributions starting in the 1980s²⁻⁵ resulted in a significant improvement in the treatment possibilities for microtia patients and set a new standard for surgical care in microtia. Further refinements in technique by others starting in the 1990s, including Nagata,^{1,6-8} Firmin et al,^{9,10} and Park et al,^{11,12} have resulted in continual improvement in surgical results. Treatment selection in microtia is still not without controversy. The lack of surgical expertise to consistently achieve good results with these new autologous techniques and the variability of surgical results have led to the development of other treatment modalities. These will be discussed further in this chapter. Several excellent reviews are available for those interested in this field.¹³⁻¹⁹

MICROTIA CLASSIFICATION AND CHARACTERIZATION

Historically, many classification systems of major ear deformities have been described, including those by Marx (1926),²⁰ Rogers (1974),²¹ and Tanzer (1977).²² Most systems describe congenital deformities and classify them according to embryonic development, from mildest to most severe deformity. These are not particularly helpful for specific surgical planning.

Weerda²³ expanded on Marx and Roger's system by trying to include all dysplasias in three categories. More recently, Hunter et al²⁴ published a paper to standardize the terminology used to describe and classify ear dysmorphology based on Weerda's system (Table 31-1). Nagata⁶ classified microtia into five types (Fig. 31-1):

1. Lobule
2. Concha
3. Small concha
4. Anotia
5. Atypical microtia

These modified classifications have some relevance for definitive surgical planning; the more descriptive the name of the ear deformity, the more helpful it is in surgical planning.

Human Disorders Associated With Microtia

Patients with microtia should be examined for other dysmorphic features. It has been reported that 20% to 60% of children with microtia have an identifiable syndrome or other anomalies (Box 31-1). These include craniofacial microsomia, Townes-Brocks syndrome, and mandibulofacial dysostosis (Treacher Collins and Nager syndromes).²⁵ Oculoauriculovertebral spectrum (OAVS) includes facial asymmetry, ear and facial tags, epibulbar dermoid benign tumors, microphthalmia, macrostomia, and microtia (Fig. 31-2). Extracranial features include renal, cardiac, and vertebral anomalies. Goldenhar syndrome and hemifacial microsomia are included in this spectrum. Most cases are sporadic with occasional genetic inheritance. There remains controversy whether isolated microtia is a mild phenotype of OAVS. The present thinking is that microtia and OAVS should be considered separate entities.

Table 31-1 Hunter Classification of Microtia: Modification of the Weerda Classification

Degree	Definition
First	Presence of all the normal ear components and the median longitudinal length more than 2 standard deviations below the mean
Second	Median longitudinal length of the ear more than 2 standard deviations below the mean in the presence of some, but not all, parts of the normal ear Replaces: Grade III dysplasia, severe cupped ear, cockleshell ear, type IV constricted ear, snail ear, shell ear, mini ear
Third	Presence of some auricular structures, but none of these structures conform to recognized ear components Replaces: Grade III dysplasia, group III hypoplastic ear, peanut ear

Fig. 31-1 Microtia types. **A**, Lobule. **B**, Conchal. **C**, Small conchal. **D**, Anotia. **E**, Atypical.

Box 31-1 Microtia-Related Anomalies

Oculoauriculovertebral spectrum disorders

Townes-Brocks syndrome
Mandibulofacial dysostosis
Treacher Collins syndrome
Nagar syndrome

Fig. 31-2 OAVS patient with microtia.

Epidemiology and Genetics

The reported prevalence of microtia varies from 0.83 to 17.4 per 10,000 births.²⁵ The etiologic factors are not clearly understood. There are two prevailing theories; the most current hypotheses for microtia include (1) neural crest cell disturbance, and (2) vascular disruption through several different mechanisms. There is evidence for a significant genetic and environmental contribution to microtia. The factors quoted include race, with a higher incidence in Asian, Hispanic, and First Nation populations, and drug usage, with a higher incidence associated with retinoic acid, alcohol, thalidomide, and mycophenolate mofetil, an anticancer medication. Microtia appears more frequently in mothers who were exposed to higher altitudes during pregnancy and those with type 1 diabetes. Mendelian inheritance is more common in syndromic and familial cases. Multifactorial or polygenic causes are more probable in sporadic cases. Microtia affects the right ear 60% of the time and is 20% to 40% more common in males.

Embryology

The middle and external parts of the ear are derived from the first (mandibular) and second (hyoid) branchial arches.²⁶ The ear is formed from six hillocks that ultimately grow and coalesce along these arches. They are first seen at 5 weeks' gestation. During the course of development, the ear forms, grows, and migrates from an antero-caudal to a posterocranial position. Ultimately, 85% of the fully formed ear is derived from the hyoid arch. Only the tragus and crus helix are derived from the mandibular arch. The canal and concha are derived from the first branchial cleft. The inner ear, first appearing at 3 weeks' gestation, has an ectodermal embryologic origin, so it is not typically involved in microtia.

PREOPERATIVE PLANNING

Initial Consultation

Early consultation helps the surgeon to develop a trusting relationship with the family. Because of their easy access to the Internet, parents may be bombarded with information that may be factual and informative, biased, or frankly deceptive. The surgeon can guide them through a discussion

of ear reconstruction and treatment options, managing expectations and at all times striving to alleviate parents' feelings of guilt.

Psychosocial Issues

The prevalence of mood disorders is high in microtia patients, with “depression” in 20.2%, “interpersonal sensitivity/social difficulties” in 36.6%, and “hostility/aggression” in 26.3%.²⁷⁻²⁹ These percentages were higher in older patients who had not undergone reconstructive surgery. The age at surgical intervention must be balanced against the potential for a good aesthetic reconstruction; a poor result may have a long-term adverse psychological effect on the individual's self-esteem. The child usually discovers he or she is different at about age 3 or 4. The earlier children are made aware that their ear is different, the lower the prevalence of psychological disorders. This is one factor to consider when discussing the timing of reconstruction. Both Brent⁵ and Jiamei et al³⁰ felt the major determinant of these psychological issues is transmission of parental guilt. Teasing, severity of microtia, low levels of maternal education, family disharmony, parental anxiety, and overprotection were all significantly associated with mood disorders in microtia patients.

Treatment Selection

The general principle of reconstructive surgery to use autologous tissue whenever possible also applies to ear reconstruction. The most common treatment choice for microtia is autologous reconstruction using costal cartilage. The surgical techniques required to obtain consistent results are very challenging and difficult to learn. This has led to a wide variety of surgical outcomes. Because of this, two alternative methods for microtia reconstruction have developed and have strong proponents. These are:

1. The use of a porous polyethylene ear framework covered by a temporoparietal fascial flap and skin graft
2. Removal of the microtic remnant, placement of osteointegrated implants, and use of a prosthesis

SURGICAL OPTIONS FOR AUTOLOGOUS EAR RECONSTRUCTION

The choice of procedure is based on the surgeon's experience and training. A reasonable result should be obtainable with any of these procedures when done correctly.

The Brent technique^{2,3,5} set the standard for surgical care of microtia starting in the 1980s. His technique consists of four stages:

1. Rib harvest and framework creation
2. Lobule transposition
3. Framework elevation
4. Tragus reconstruction, conchal excavation, and contralateral otoplasty, if needed

Further evolution in technique led by Nagata,^{7,8,31} Firmin,⁹ and others^{12,32,33} has led to fewer surgical stages with a more complicated three-dimensional (3D) framework design. They have also changed the approach to soft tissue management of microtia. Their first stage combines framework creation, lobule transposition, and tragal reconstruction. The second stage is elevation of the framework, placement of a cartilage block under the framework to help maintain projection, and coverage with a temporoparietal flap and a split-thickness skin graft from the scalp. Proponents of these newer techniques cite improved contour of the reconstructed ear, including better definition of the tragus, antitragus, antitragal notch, and antihelical fold. They also think there

Table 31-2 Comparison of Autologous Ear Reconstruction Techniques

	Age at Harvest	Side of Harvest	Framework Construction	Plane of Rib Dissection	Fixation Technique	Postoperative Dressings	Number of Stages
Brent ⁵	5 or 6	Contralateral	Two piece	Supraperichondrial	Nylon suture	Suction drains	4
Nagata ⁶	10 (or when the circumference at the xiphoid process is 60 cm)	Ipsilateral	Five piece	Subperichondrial	Stainless steel wires	Bolsters	2
Firmin ⁹	10	Ipsilateral	Five piece	Subperichondrial	Stainless steel wires	Suction drains	2

is better projection using cartilage during the framework elevation stage. Critics argue that the complication rate is higher, the techniques more difficult to learn, and the potential for chest wall deformity is higher. These three approaches are summarized in Table 31-2. Other autologous techniques and modifications used are based on the techniques of Brent,⁵ Nagata,⁶ and Firmin.⁹

Templating

Preoperative planning requires creation of intraoperative templates for positioning the new ear as well as creating the new 3D framework. The anatomic position of the reconstructed ear is a constant measure shared by all techniques. Proper placement of the new ear is a key step in creating a natural appearance. The ear should be placed according to appropriate anatomic landmarks, regardless of the position of the hairline or an existing remnant. If a compromise is to be made, it is important to note that an abnormal inferior-anterior position is more noticeable, so movements in these directions should be limited. Absolute measurements may need to be compromised in patients with facial asymmetry so that the ear fits in the relative correct position based on facial features.

In unilateral microtia, ear positioning is guided by the normal contralateral side. An x-ray film or other transparent celluloid material is placed on the nonmicrotic side of the patient's face and the ala, lateral canthus, eyebrow, lateral commissure, and normal ear are traced. This positioning template can then be superimposed on the microtic side of the face to reveal the correct relationship of these landmarks to the site of the future reconstructed ear (Fig. 31-3).

An ear template can be created by tracing the outline of the normal contralateral ear or a 3D model of the ear on a transparent film paper and then drawing the underlying "ear skeleton," removing 1.5 to 2 mm to account for the future thickness of the mastoid skin coverage (Fig. 31-4). Nagata has created a series of templates based on the normal anatomic relationships and dimensions of the ear (S. Nagata, personal communication, 2015). These templates come in varying sizes from 55 to 70 mm (Fig. 31-5). He chooses one that is 2 mm shorter than the normal opposite ear. He does not use the contralateral normal ear as a template.

Advanced digital technologies can provide the surgeon with 3D models of the "new" reconstructed ear using a moulage, CT scan, or laser scan of the normal ear and then reversing it. In patients with bilateral microtia, placement of the ear becomes a more difficult task. Templates

Fig. 31-3 Ear positioning. **A**, Using a clear template. **B**, Using an acrylic template.

Fig. 31-4 Two-dimensional transparent film template and 3D model.

Fig. 31-5 Classic Nagata 60 mm template. (Courtesy of S. Nagata, MD, PhD.)

must be created so that consistency can be achieved on both sides. The actual ear template can be chosen from other patients or made from a family member's ear. A smaller ear (55 to 60 mm) is usually chosen, because less cartilage will be needed and less potential stress will be put on the skin envelope.

Rib Harvest Techniques

Rib is harvested with the patient in the supine position; harvesting can be done in the same procedure with preparation of the auricular pocket.³⁴⁻³⁶ The resultant chest wall deformity after rib harvest is a concern for critics of autologous reconstruction. Several authors have described a strategy to try to mitigate this concern.³⁷⁻³⁹ The incision is generally placed in a transverse or oblique orientation on the chest wall. The exact site and length of the incision can vary, depending on which ribs are harvested and the number of ribs required. Generally, the incision is made over the seventh rib and is a minimum of 5 cm in length (Fig. 31-6). In older females with mature breast development, the incision can sometimes be hidden in the inframammary fold. During rib harvest it is preferable to leave the rectus abdominis and external oblique muscles intact if possible, because transection of these muscles increases postoperative pain. Cautery should be used very judiciously on the perichondrium, since heat is damaging to chondrocytes and will cause later cartilage resorption.

The Brent technique⁵ uses a lower profile two-piece framework that requires less costochondral cartilage than other autologous techniques and thus can be performed in patients at a younger age, typically at age 5 or 6. Generally, the contralateral sixth, seventh, and eighth ribs are harvested. Dissection is performed in an extraperichondrial plane. Brent leaves a superior rim of the sixth rib to minimize chest wall deformity. In our experience, the incidence of an inadvertent pleural tear is higher with an extraperichondrial harvest than a subperichondrial harvest.

Creating the larger Nagata 3D framework⁶ requires more cartilage. He recommends delaying reconstruction until the patient has a total chest circumference of 60 cm measured at the xiphoid process, usually at about age 10. We have performed this technique on patients as young as 8 years of age if their chest circumference was adequate. The ipsilateral sixth, seventh, eighth,

Fig. 31-6 Landmarking the site for chest incision.

and occasionally ninth ribs are harvested in a subperichondrial fashion. Specialized instruments are available to elevate the perichondrium, which minimizes damage to the underlying cartilage (Fig. 31-7). The perichondrial sleeve is carefully incised down its midline but is otherwise left in situ. The only perichondrium excised is that which immediately overlies the sixth and seventh synchondroses.

During harvest, utmost care should be taken when handling the rib cartilage. The ribs are quite strong when traction is applied in a longitudinal direction, but flexing the rib can result in breakage. This is most likely to occur if the rib has been inadvertently nicked during dissection or has small areas of calcification or spongy deterioration within it (Fig. 31-8).

To try to minimize chest wall deformity, any cartilage pieces left over after the framework has been reconstructed are then diced into small pieces and either reintroduced into the perichondrial sleeve, or more recently, surgeons have placed them in a Vicryl mesh sleeve, making a

Fig. 31-7 Subperichondrial rib harvest with gouge.

Fig. 31-8 Harvested ribs.

Fig. 31-9 Pseudorib with Vicryl mesh sleeve.

pseudorib (Fig. 31-9). There is some evidence to suggest that this decreases the resultant chest wall deformity. Some surgeons, before skin closure, will bank a crescent-shaped wedge of cartilage subcutaneously in the incision site for future harvest during the second stage of reconstruction. Kawanabe and Nagata³⁸ often later use the cartilage regenerated within the pseudorib for framework elevation. Firmin's approach to harvesting^{9,10} is quite similar to Nagata's.

During rib harvesting the surgeon must be careful to avoid entering the pleural space. If the parietal pleura has been injured, it can be easily managed by inflating the lung, suctioning out the air, and closing the pleural defect. A chest tube is not needed unless the visceral pleura has been injured. Pain at the donor site can be mitigated with either an intercostal block or an indwelling local anesthetic catheter during the postoperative period. Drains are not usually necessary and add to the patient's chest discomfort.

Ear Framework Creation

Carving rib cartilage is best performed at a separate table using a combination of scalpel and gouges (Fig. 31-10, *A* and *B*). The finished framework should be devoid of sharp edges and have the appearance of a single, unified, sculpted piece. The pieces of the framework are fastened together using either suture material (Brent⁵) or double-armed stainless steel wire (Nagata⁶ and Firmin⁹) (Fig. 31-10, *C*). Regardless of the fixation used, the ends of the fixation material must not be exposed on the anterior surface of the framework, since this would increase the risk of extrusion.

Brent Framework

The Brent framework includes a base frame carved from the sixth and seventh ribs and a helical rim carved from the eighth rib.⁵ The contours of the antihelix are achieved by using a gouge to create the corresponding areas of relief on the base framework. No additional cartilage is added. The helical rim sits around the base frame and is sutured in place with horizontal mattress sutures of 4-0 clear nylon (Fig. 31-11).

Fig. 31-10 A, Instrument setup for carving rib cartilage. B, Specialized gouges. C, Stainless steel wires.

Fig. 31-11 Example of the Brent framework.

Fig. 31-12 Nagata framework. **A**, Cartilage frame. **B**, Paper template. (Courtesy of S. Nagata, MD, PhD.)

In Brent's classic description,² the tragus was not part of the initial framework. It was instead created from a composite graft from the contralateral conchal bowl during the fourth and final stage of reconstruction. Brent in some cases will add a tragal strut to his framework, which is particularly useful in cases of bilateral microtia.

Nagata Framework

Nagata uses a five-piece framework constructed from the sixth to ninth ribs.⁷ This framework includes a base frame, a helical rim, an antihelix, a tragal extension, and a conchal bowl graft for added projection (Fig. 31-12). In cases in which the skin pocket is tight or added projection is not needed, the conchal bowl unit can be omitted.

Pieces are affixed to the base frame with double-armed straight needle sutures of 38-gauge stainless steel wire. The wires are twisted and cut on the posterior surface of the framework. The loop of wire on the external surface is countersunk. Further definition is achieved by using a gouge to deepen the regions of the scapha and fossa triangularis on the base frame. Nagata has demonstrated his method of framework construction in the accompanying video entitled Ear Reconstruction: Nagata Framework.

Firmin Framework

The Firmin framework is similar to Nagata's, except Firmin does not carve a conchal unit but rather includes a "surélévation" (elevating) piece.⁹ This piece spans the root of the helix and the tragus and is attached to the posterior surface of these structures. The purpose is to give more projection and stability to the tragus and the root of the helix, because the contractive forces on the framework often cause blunting of these features. Firmin demonstrates her method of framework construction in the accompanying video entitled Ear Reconstruction: Three-Dimensional Costal Cartilage Frame.

Incisions and Soft Tissue Management

Correct surgical planning of incisions, meticulous dissection of the auricular pocket, and gentle handling of the surrounding soft tissues are critical components of successful ear reconstruction. Once the surgeon has perfected the skill of carving an ear framework, soft tissue management becomes the major determinant of aesthetic success in reconstructing an ear.

The microtic cartilaginous remnant is of no value and is always excised during the creation of the auricular pocket. The type of incision used to create the auricular pocket varies, depending on the ascribed technique and the type of microtic deformity. Postoperative management of soft tissue in all techniques is largely focused on skin circulation and preventing seroma or hematoma formation. This complication will thicken and fibrose the skin flap, blunting auricular definition and downgrading the aesthetic result.

In the first stage of the Brent technique^{2,5} the lobule is left in situ, and a longitudinal skin incision is made posterior to the auricular vestige. A thin skin flap is elevated, taking care to preserve the subdermal vasculature and the microtic cartilaginous remnant is removed. The pocket is further developed to 1 cm outside the ear markings. The two-piece framework is introduced into this pocket. Skin is closed over two suction drains, one beneath the framework and the other adjacent to the helical rim. Epinephrine solutions are not used so that skin circulation can be evaluated during the procedure. Brent feels the use of skin bolsters increases the risk of skin necrosis (Fig. 31-13).

Nagata^{6,7} was the first to describe a skin incision technique that would allow rotation of the lobule and creation of an auricular pocket in a single stage. A W-shaped incision is placed along the border of the mastoid region, extending vertically on the posterior aspect of the lobule, crossing the lobule anteriorly, and ending in a small 2 mm circular incision that forms the U-shaped configuration of the intertragal notch. These incisions unfold to form three flaps, the anterior and posterior skin flaps of the tragus and the anterior skin flap of the lobule⁶ (Fig. 31-14).

Fig. 31-13 Brent framework with suction drains.

Fig. 31-14 Nagata W-shaped incision. **A**, The incision with a pedicle. **B**, The incision with remnant removed.

A small subcutaneous pedicle is left above the central limb of the W flap.⁶⁻⁸ The pedicle has been demonstrated to enhance the blood supply to the skin flaps.^{39a,39b} The remnant is then removed and a slightly oversized auricular pocket is dissected. Once the skin flaps and auricular pocket are created, the tragal portion of the framework is tucked around the subcutaneous pedicle, and the superior portion of the framework is rotated into the remainder of the pocket. If the addition of a tragal strut or “surélévation” piece, as described by Firmin,⁹ is desired, this piece must be fixed after the placement of the framework in the pocket.

The W incision can be modified for cases of small and large conchal-type microtia. The skin incision for a small conchal-type microtia³¹ is virtually identical, except that the anterior lobular incision must be placed posterior to the indentation created by the small concha. The incision modifications required for the large conchal-type microtia are more dramatic.⁸ The tragal and lobular portions of the ear are intact and are thus not reconstructed in the 3D framework. The posterior skin incision has a similar W-shape but is placed more superiorly and is extended anteriorly across the helix to the antihelix, terminating on the posterior conchal wall.

Nagata⁶ uses temporary suction to hold the skin flaps in position against the framework and then places bolsters. The bolster dressing is checked every day, and antibiotic ointment is applied daily. Bolsters are kept in position for 10 to 14 days (Fig. 31-15). The flaps created bring more tissue transversely across the framework, so the skin is under less tension when the bolsters are placed. In our experience, if skin necrosis is to occur with the Nagata technique, it is most likely to occur on the posterior aspect of the tragus at the tip of the W flap. In the Brent technique, it is more likely to be over the helical rim.

Firmin has developed an algorithm for incision choice based on size and shape of the remnant.¹⁰ A type 1 incision for classic lobular-type microtia is like a Z-plasty with the lobule as one of the flaps. A type 2 incision for conchal-type microtia is transversely oriented at the midpoint of the remnant and includes a backcut to allow closure of the posterior incision to the mastoid skin. Firmin¹⁰ does not maintain a subcutaneous pedicle. Fig. 31-16 demonstrates the Brent, Nagata, and Firmin approaches for skin incisions of lobular-type microtia; the Nagata and Firmin approaches for small conchal-type microtia; and a universal approach for anotia.

Other Reconstructive Stages

The second stage in the Brent technique^{2,5} consists of rotating the lobule from a vertical to a horizontal position. The framework is elevated in the third stage. Initially Brent used a split-thickness skin graft to cover the posterior aspect of the framework after elevation, but because of the loss of the sulcus and projection, he changed his technique. An incision is made posterior to the framework and a banked piece of cartilage from the chest wall or behind the ear is retrieved. This wedge of cartilage is placed under the framework and is covered with a retroauricular fascial flap. A full-thickness skin graft is then harvested from the lower abdomen or groin and placed over the auricular sulcus defect.

The fourth and final stage is tragal reconstruction, conchal excavation, and, when necessary, reduction of the contralateral ear for improved symmetry. The tragus is constructed from a composite skin-cartilage graft from the contralateral ear and is inserted along a J-shaped incision placed at the posterior tragal margin. Some surgeons think that this often produces an unnatural appearance with an acute intertragal notch and poor definition of the conchal bowl (Fig. 31-17).

Fig. 31-15 Bolster dressing.

Fig. 31-16 Skin incisions for lobular-type microtia. Brent (*green*), Nagata (*red*), and Firmin (*blue*) approaches. **A**, Posterolateral view. **B**, Anterolateral view. **C**, Small conchal-type. **D**, Anotia.

Fig. 31-17 Tragus reconstructed with contralateral conchal bowl graft.

By adding a tragal unit to the 3D framework and creating a skin flap that naturally incorporates transposition of the lobule, Nagata was able to successfully combine the first three stages of the Brent technique into a single stage. Elevation of the framework is performed in the second stage, 6 to 12 months after the first stage. An incision is made 5 mm posterior and superior to the framework, and the framework is undermined to the level of the conchal bowl. The previously banked crescent-shaped rib graft is retrieved from the chest wall incision site, placed under the 3D construct, and fixed in place.

Next, a thin ultradelicate split-thickness skin graft (UDSTS) is harvested from the scalp using a No. 15 blade scalpel or dermatome. This graft is harvested well above the level of the hair follicles and produces a thin graft that is an acceptable color match. A temporoparietal fascia flap (TPF) is harvested through a zigzag or transverse incision and tunneled subcutaneously to cover the posterior surface of the projected auricle. The UDSTS is sutured in place over the TPF flap and further secured with a bolster dressing (Fig. 31-18).

The Firmin technique¹⁰ also involves two stages. Firmin advocates aggressive framework elevation. The banked wedge of cartilage is fixed to the undersurface of the framework at the level of the antihelix. The posterior skin is advanced and affixed to the depth of the sulcus. The exposed auricle is then covered with a TPF flap. A split-thickness skin graft is harvested from the scalp using a dermatome and is cut into two grafts. One graft is placed on the posterior aspect of the auricle and the other is placed on the mastoid surface.

Chen et al⁴⁰ describes a technique elevating a thin split-thickness skin graft from the hair-bearing scalp in continuity with the full-thickness skin posterior to the ear to cover the TPF, avoiding some visible scarring. A study comparing several techniques of sulcus construction showed no difference in ear elevation at 3 months.⁴¹

Regardless of the technique used, primary graft take is crucial to prevent secondary wound contraction and loss of projection. Because of the variability of results after ear elevation and deterioration of the aesthetic outcome, some surgeons have abandoned this second stage⁴² (Fig. 31-19).

Fig. 31-18 Second-stage elevation with a cartilage graft and a TPF graft. **A**, Harvest of the TPF flap. **B**, Transposition of the TPF flap to cover the costal cartilage graft.

A BAHA cochlear implant is placed at the time of the second stage. **A**, Lobular-type microtia vestige. **B**, Completed cartilage framework. **C**, The skin flaps elevated before placement of the framework. **D**, At closure, the skin flaps drape into the contours of the cartilage, aided by a suction drain. **E**, A bolster dressing further contours skin to cartilage. **F**, The BAHA guide, shown at the time of the second-stage elevation of the reconstructed ear. **G**, The temporoparietal fascia flap. **H**, The banked cartilage graft in place and covered with the temporoparietal fascia flap. **I**, The scalp donor site and the split-thickness skin graft in place over the postauricular fascial flap and remainder of the postauricular sulcus. **J**, The skin graft covered with a bolster dressing, and a dressing on the donor site at completion of the second stage. **K**, The completed reconstruction showing the sound processor in place. **L**, The BAHA abutment with the well-healed skin graft visible on the postauricular surface.

Patients With Low Hairlines

It is not uncommon to have a small amount of hair growth on the superior edge of the reconstructed ear. If the amount of hair growth is limited, this can be managed by trimming, laser therapy, or electrolysis. In cases of true low hairline, appropriate ear positioning is not compromised. Laser hair removal can be done before any surgical intervention is undertaken. Nagata describes a technique in which the auricular pocket is raised as an inferiorly-based flap with the hair-bearing portion raised as an UDSTS graft. The superior portion of the framework is then resurfaced with a TPF flap and covered with the attached UDSTS (Fig. 31-20).

Secondary Cases

Not all reconstructed ears are aesthetically acceptable. Poor results can occur from a surgeon's inexperience or complications such as hematoma, major infection, or skin necrosis. Patients are often reluctant to undergo a repeat costal cartilage graft harvest. Treatment of failed autologous ear reconstructions is a difficult challenge and speaks to the importance of achieving a satisfactory result the first time.

Autologous salvage procedures require either partial or complete reconstruction of the 3D framework. Rib harvest is performed on the opposite side of the original harvest to ensure a sufficient amount of cartilage is available. The skin flaps are often thick and fibrosed and offer limited coverage of the new framework. If the TPF flap is still intact, this flap can be raised and used to cover the framework, followed by a split-thickness skin graft.⁴³ If the TPF flap is unavailable, the deep temporoparietal fascia can be used, but it is less reliable. The chances of achieving a reasonable aesthetic result in this setting are much more challenging (Fig. 31-21). Soft tissue expanders can occasionally be of benefit to provide some coverage for expanding nonscarred skin only.⁴⁴ Expanding scarred skin or skin grafts has a high complication rate and cannot provide the quality of skin required in ear reconstruction.

Another option includes removal of the ear reconstruction, followed by placement of osteo-integrated implants and creation of an ear prosthesis (Fig. 31-22).

Other Reconstructive Options

Porous Polyethylene Frameworks

Because of concerns of chest wall morbidity, the challenge of carving an ear framework, and the variability of surgical results, alternative methods of ear reconstruction have been explored. Early alloplastic frameworks such as Silastic are no longer used because of the potential for long-term complications, including infection and extrusion. The use of porous polyethylene for the framework initially had similar problems. However, Reinisch, a pioneer in the use of porous polyethylene, has refined the technique to include complete coverage of the framework with a TPF flap in all cases.⁴⁵ The TPF flap improves the vascularity of coverage, decreasing the complication rate. It also allows some movement of the graft over the framework, which may have a protective effect. He has shown excellent aesthetic results obtained at an earlier age⁴⁶ (Fig. 31-23).

Reinisch⁴⁵ often harvests the large TPF flap using an endoscopic technique through a post-auricular incision. The TPF flap must be of sufficient size to cover the framework in its entirety. The auricular skin pocket is also dissected from this same incision. A splint is placed over the reconstruction initially to reduce the risk of seroma or hematoma. He has had success with both low hairline and secondary reconstructions.

The advantage of this approach is that it is a one-stage procedure performed on an outpatient basis with no rib harvesting. Critics argue that it invites less-experienced surgeons to attempt ear reconstruction, yielding poor results.⁹ It uses the valuable temporoparietal fascia, making it unavailable for any salvage procedures. They would argue that Reinisch's results are hard to duplicate, and late extrusion of the alloplastic framework is always a possibility. Long-term studies will help to further define the role of these treatment options in the management of microtia.

Osteointegrated Prosthetic Reconstruction

Osteointegrated implant-retained (OPR) prosthetics are a useful treatment option in adults with major ear deformities from a variety of different causes, but their use in children with microtia is controversial.^{46,47} The procedure requires removal of the ear remnant and creates scarring in the region of the ear, severely compromising future autologous options. Children may have an intermittent soft tissue reaction around the abutments and will need a new prosthesis every 2 to

Fig. 31-23 Ear reconstruction with porous polyethylene. **A**, Preoperative view. **B**, Postoperative result. (Courtesy of J. Reinisch, MD.)

Fig. 31-24 Secondary reconstruction with a prosthesis. **A**, Failed Silastic framework. **B**, Salvage with a prosthetic ear.

5 years for the rest of their lives. Most reconstructive surgeons would much prefer autologous ear reconstruction as the treatment of choice for microtia in children. An adhesive-retained ear prosthesis should not be considered as a trial for an implant-retained prosthesis. It does not accurately demonstrate to the patient the advantage of osteointegration to overcome the significant problems with adhesives (Fig. 31-24).

OUTCOMES

Assessing surgical outcomes is difficult. Perceived results as judged by the patient, family, surgeon, and unbiased observer can be quite different. The psychological outcome of treatment is just as important as the aesthetic result to the patient's overall recovery.

The results of autologous reconstructions have been published.^{32,48-51} Although the overall satisfaction is reported to be high, there are certainly weaknesses in the methods of evaluation. There is no consistent, validated method to evaluate surgical results or to allow comparison of techniques. There is a definite improvement from a psychological point of view.⁵² In 69% of patients, the ear became part of the patient's body image, and 88% would choose autologous reconstruction again; 68% felt the chest scar was "absolutely acceptable."²⁹ Patients younger than 20 years of age at the time of surgery experienced more improvement in self-esteem and psychosocial attitudes with surgical reconstruction.²⁹

Surgical complications such as skin necrosis and hematoma should occur infrequently. These need to be treated early and aggressively to minimize cartilage resorption (Fig. 31-25). Extrusion of a suture is easily corrected by removal. Critics of autologous reconstruction would argue that the results published are only the best results and are not necessarily obtainable by surgeons performing smaller volumes of procedures. However, when the surgery is properly performed by an experienced surgeon, a satisfactory, stable, autologous ear reconstruction should be possible in most cases. The overall experience and training of the surgeon is probably more important than the specific technique used.

Fig. 31-25 Skin necrosis complication. **A**, Necrosis at the tip of a W flap. **B**, Healed tragal necrosis. **C**, Helical rim necrosis. **D**, Helical rim necrosis healed by secondary intention.

Using porous polyethylene, a high satisfaction rate has also been achieved with an aesthetically acceptable outcome in 85% of children.⁵³⁻⁵⁵ The Glasgow Benefit Inventory (GBI), which measures health-related quality of life, was elevated (21.2) but was not as high as in the autologous group (48.1). Surgical complications decreased when complete coverage of the framework was achieved with a TPF flap. A 2.7% framework fracture rate and a 7.3% exposure rate was reported.⁵³

Osteointegrated prosthetic ear reconstruction has also demonstrated high levels of success in patients of all ages.^{46,47} Psychologically, the prosthesis becomes part of the body image in the majority of patients. Issues related to prosthetic shape, color, means of attachment, and long-term implant stability are minimal. The disadvantages of this approach in children are possible intermittent chronic soft tissue problems around the percutaneous abutments and the ongoing need for a replacement prosthesis.

Tissue Engineering and Composite Tissue Allotransplantation

The future of ear reconstruction rests with advances in tissue engineering.⁵⁶⁻⁶⁴ No material presently available, autologous or alloplastic, completely mimics the characteristics of auricular cartilage. While tissue engineering offers great promise, major hurdles remain. The first problem is

to create a 3D scaffold onto which cartilage cells can anchor and grow. The use of 3D computer-aided design and manufacturing has helped in the creation of very accurate scaffolds. Biological scaffolds mimic cartilage extracellular matrix. Natural materials like hydrogel and hyaluronic acid have been tried but are limited by poor strength and by long-term degradation. Synthetic polymers have the advantage of being customizable: the designer can control the porosity, shape, and permeability of the polymer. However, they do elicit an immunologic response and lack the surface characteristics favoring cellular attachment and growth.

The second issue is populating the scaffold with chondrocytes. One hundred million cells are needed to create an adult ear. Chondrocytes, both autologous and xenogenic, have been used. Auricular and nasal chondrocytes yield more cartilage at a faster rate than auricular cartilage and have superior histologic and biochemical properties. Continued problems remain regarding de-differentiation of cells, limited donor supply, and a short time frame for proliferation. Uncontrolled cell proliferation and potential tumor growth are still concerns. The use of new “smart” scaffolds of nanocomposite polymers with surface modifications to stimulate and control cell attachment, growth and differentiation, and propagation of stem cells may be the way of the future. The problems of skin coverage of the framework and its effect on the ultimate aesthetics will still prove to be a challenge. There have been early reports of use in humans.⁶⁵

The potential for composite tissue allotransplantation in ear reconstruction has been explored from an anatomic perspective.⁶⁶ Long-term challenges of immunosuppression remain to be solved. Its potential use in adults following trauma is much more likely than for correction of microtia in children.

HEARING RESTORATION IN THE MANAGEMENT OF MICROTIA

Ideally, reconstruction of microtia should include both the external ear and restoration of hearing. Many otologists have attempted to restore hearing by creating an external ear canal and reconstructing a tympanic membrane and ossicles to stimulate the normal inner ear.⁶⁷⁻⁶⁹ However, few otologists can consistently restore near-normal hearing.⁷⁰ Complications are high, including frequent restenosis of the canal and recurrent infections. Creating an ear canal risks injury to an aberrant facial nerve. It also causes scar formation in the area of future auricular reconstruction, compromising the final aesthetic result.

The first bone-anchored hearing device (BAHD), introduced in Sweden in 1977,⁷¹ changed the hearing options for children with microtia. These hearing devices are held in position to the mastoid bone by an osteointegrated implant. They allow direct stimulation of the cochlea, which is normal in most microtia patients.⁷¹ Unlike a canaloplasty procedure, this operation does not depend on a functioning middle ear or patent canal and is a much simpler and safer procedure. BAHDs are the benchmark against which newer hearing modalities are measured.⁷²

Bilateral microtia occurs in 10% of patients.²⁵ The significant hearing deficit of these individuals requires early hearing restoration. Our patients are offered the option of trying a BAHD (BAHA Softband) starting in the early newborn period (Fig. 31-26). Surgical placement of a BAHD typically occurs at age 5, when the thickness of the mastoid bone is sufficient for a titanium implant. The most common surgical practice is to place a unilateral BAHD, even in bilateral microtia, because a single hearing aid will stimulate both cochleas simultaneously. Placement of bilateral BAHDs is being investigated⁷³; recent evidence suggests that this results in better hearing sensitivity, speech perception, sound localization, and lateralization, as well as improved patient perception of overall sound quality and quality of life.⁷⁴⁻⁷⁷

The application of a BAHD in unilateral microtia patients is less clear, since there is a commonly held belief that these patients do not require hearing restoration. However, there is con-

Fig. 31-26 OAVS patient wearing a BAHA Softband hearing device.

Fig. 31-27 Autologous reconstruction with BAHD.

siderable evidence to suggest that untreated unilateral hearing loss causes deleterious effects to the education and behavioral development of these children. This warrants reevaluation of traditional practice and study of hearing restoration with a BAHD.⁷⁸⁻⁸⁴

Advances in percutaneous, transcutaneous, and completely implantable hearing devices will give patients with microtia new hearing options.⁸⁵⁻⁸⁸ The long-term success and effects of such devices on autologous reconstruction still requires further evaluation. The ability to upgrade and change the hearing hardware in the future needs to be considered when discussing current treatment options with the patient and their families.

Autologous Ear Reconstruction and Bone-Anchored Hearing Devices

A team approach is needed to satisfy the needs of both the otologist and the reconstructive surgeon. Appropriate placement of the bone-anchored hearing device is crucial both for hearing and to avoid scarring at the future site of autologous reconstruction.⁸⁹ The distance the bone-anchored hearing device should be sited from the pseudoauditory meatus is not well established. Our placement has averaged 5.6 cm from the pseudomeatus. There was no significant difference in positioning or complications whether or not the implant was placed before or after autologous ear reconstruction (Fig. 31-27).

Another challenge is the timing of each operation. The pediatric otologist would prefer that the bone-anchored hearing device be implanted before school age (around age 5) to prevent any

deleterious developmental effects of hearing impairment. The plastic surgeon would prefer that the autologous reconstruction be done before implant placement (age 8 to 10) to decrease the risk of skin complications or future ear-positioning issues.

LEARNING TO PERFORM MICROTIA RECONSTRUCTION

One of the reasons for the inconsistency in surgical results has been related to challenges in training surgeons to do the procedures.⁹⁰ Traditional surgical teaching has usually included some form of observership but has lacked “hands on” experience. Costal cartilage from the sixth, seventh, and eighth ribs presents unique challenges of shape, form, and consistency that are not captured in traditional training models.^{91,92}

Better hands-on training simulations, including rib and multipiece ear framework models, have become available to test the surgeon’s aptitude, commitment, and skill level⁹³⁻⁹⁵ (Fig. 31-28). The authors of this chapter have developed an app available at iTunesU (<http://www.apple.com/education/ipad/itunes-u/>) to teach the intricacies of ear carving using a step-by-step approach

Fig. 31-28 Rib models. **A**, Sterilizable ear carving models. **B**, Rib model with carved framework.

Fig. 31-29 iPad application for teaching microtia reconstruction.

(Fig. 31-29). This application aims to shorten the learning curve for surgeons. It will also dissuade those unable to create an accurate three-dimensional ear framework on a model from actually operating on a patient. Also available are several surgical videos by leaders in ear reconstruction demonstrating their techniques to create an ear framework from rib cartilage.^{16,18}

Surgical simulation and the use of models are playing an increasing role in surgical education.⁹⁶ Surgical simulation studies particularly in general surgery and urology have led to the development of four principles we think are applicable to microtia training:

1. Mandatory participation
2. Proficiency-based learning (not simply time or numbers based)
3. A distributed training schedule (not a weekend course)
4. Overtraining

These concepts have been applied to athletes, musicians, and pilots and would likely benefit reconstructive ear surgeons as well. Simply watching an experienced surgeon perform ear reconstruction is not a substitute for practiced skills. It is no longer acceptable to just “give it a try” if the surgeon has not demonstrated some proficiency using an ear-carving training model or its equivalent.

This sensible approach to surgical education will result in fewer but better trained reconstructive surgeons. They will be performing autologous ear reconstruction with better and more consistent outcomes.

CONCLUSION

Ear reconstruction continues to be a challenging, dynamic field of reconstructive surgery. Results will improve only with improved educational efforts and specialized surgeons offering this form of reconstruction. Developments in tissue engineering and advanced digital technologies offer the greatest hope for future improvements in the care of patients with microtia.

KEY POINTS

- There are several classification systems used to describe microtia based on the degree of ear deformity. The more descriptive the classification system, the more relevant and useful it is for surgical planning.
- Microtia is often associated with an identifiable syndrome. Clinicians should be aware of this so that a thorough workup is performed to rule out additional anomalies.
- There are three methods currently used for ear reconstruction: autologous reconstruction with costal cartilage, reconstruction with a porous polyethylene framework (such as Medpor), and an osteointegrated implant-retained prosthesis.
- Autologous reconstruction using costal cartilage has evolved over time. The most recent techniques require more cartilage to produce a more elaborate 3D framework.
- Care must be taken to confirm the correct position of the newly constructed ear based on anatomic landmarks and facial features. A poorly positioned ear will yield a suboptimal result regardless of the appearance of the ear itself.
- The costal cartilage framework can be carved based on templates traced from the normal contralateral ear, in the case of a unilateral microtia, or it can be carved based on prefabricated templates designed by Nagata.^{7,8}
- In general, the sixth, seventh, and/or eighth ribs are harvested for construction of the 3D framework. Resultant chest wall deformity can be mitigated by reintroducing the diced leftover cartilage into a pseudorib of resorbable mesh and placed in the perichondrial sleeve.
- Regardless of the technique used, delicate handling of soft tissue during reconstruction is imperative. The framework, be it cartilaginous or synthetic, must be covered with healthy, well-perfused tissue in order to prevent exposure of the framework. For porous polyethylene (PPE or Medpor) reconstruction, the framework must be covered in its entirety with temporoparietal fascia.
- Most autologous methods of reconstruction require more than one stage. Elevation of the framework is generally reserved for a second or later stage to avoid undue tension on the skin pocket at the primary procedure, which would risk skin necrosis.
- Autologous ear reconstruction is more technically difficult in syndromic patients (especially those with mandibular hypoplasia), low-hair-bearing patients, and in secondary cases.

Continued

KEY POINTS (continued)

- Each type of ear reconstruction has its own individual merits. The mode of reconstruction chosen should be based on patient factors as well as surgeon experience.
- If restoration of hearing is being considered, there needs to be careful communication and planning by all surgeons involved to ensure that the procedures do not interfere with one another in terms of aesthetic result and function.
- All of the reconstructive techniques described in this chapter can produce a pleasing aesthetic result when performed by an experienced surgeon. However, gaining this experience is difficult; it requires mentorship and practice. Surgical models have been developed to allow the inexperienced surgeon to learn the skill of carving outside of the operating room. We highly recommend that surgeons interested in learning ear reconstruction take the necessary time and steps to become proficient before embarking on a reconstructive ear case.

Nonmicrotia

Bruce S. Bauer

Bauer Otoplasty Technique.

As varied as individuals are, ears vary in their size, prominence, and shape. These variations are recognized as “normal” as long as the size of the ear is in balance with the other facial features and in a correct relationship to them.¹⁻³ In this increasingly visual world, when the media wish to depict an oddball character, a less intelligent individual, or a “funny-looking kid,” they often select subjects with large, prominent, or oddly shaped ears. Regardless of what we may later learn about these characters, we initially assign a level of immaturity or low intelligence to them. Even minor disturbances in balance or minor abnormalities in shape are immediately perceived as looking “wrong,” and this perception can become the source of significant peer ridicule. Macgregor⁴ noted, “For the child with microtic, protruding, or lop ears, for instance, such an abnormality may be the source of intense shame and anguish.” These concerns often persist well into adulthood if the deformities are not corrected, despite the fact that as an adult the individual may have developed good coping mechanisms. Not surprisingly, altering these abnormal features to a size or shape that “looks right” can have a remarkably beneficial effect on a child’s self-esteem and body image.^{2,4}

Given the well-established fact that the ears reach near-adult size and proportions relatively early in the overall scheme of facial growth and development,⁵ the previously described concerns underscore the need for timely evaluation and treatment. Although I do not advocate early correction of ear deformities to appease overanxious parents, we must recognize that it is not uncommon to see adult patients who present for correction of congenital ear deformities who wish that their parents had allowed these deformities to be corrected when they were young children. It is therefore essential that, when considering the timing of ear reconstruction, we balance what we know about ear and facial growth, available donor tissue for reconstruction, and the capabilities of children to both tolerate a corrective procedure and follow the appropriate postoperative routines.

In this chapter I describe my approach to both the analysis and treatment of the more common nonmicrotia ear deformities, and I lay the groundwork for applying these techniques to rare and unusual deformities that come along. Discussing the techniques used to treat congenital deformities has a direct bearing on treating acquired deformities, something that will become quite apparent in the following chapter. Although I will review the common numbers and measurements given for normal ears, I think that one should concentrate on recognizing the elements of protrusion, excessive size, distortion of parts, and position abnormalities that require correction to establish an appearance for a reconstructed ear that appears “right.”

EAR ANATOMY

The external ear consists of a three-tiered cartilaginous framework with adherent skin on its anterior surface and more loosely applied skin on its posterior surface. The three tiers of delicate cartilage form the helical-lobular complex, the antihelical-antitragal complex, and the conchal complex. The normal complete ear includes the scapha, concha, helix, antihelix, tragus, and lobule. The antihelix, antitragus, lobule, and Darwin's tubercle may be absent or poorly developed, yet distortion or absence does not always result in an abnormal-appearing ear^{1,2} (Fig. 32-1).

Although there are wide variations in the proportions, projection, and position of the ears among individuals, and even in a single individual, it is important to have some guidelines for establishing the degree of abnormality present. Tolleth¹ summarized the more pertinent numbers, and these are reviewed here (see Fig. 32-1).

- *Axis:* The line passing through the longest dimension of the ear is the axis. Although it is often considered to lie parallel to the nasal bridge, an angle of 20 degrees between these structures is more correct in most people. It is most important to recognize that the axis of the ear is rarely vertical.
- *Position:* When the head is in an anatomically vertical position, the top of the ear should be on a line with the top of the brow, and the bottom of the ear should be on a line at the base of the columella or slightly lower. The ear is positioned approximately one ear length (6.5 to 7.5 cm) posterior to the lateral rim of the orbit.
- *Size:* Wide variations also exist in the standard methods of measuring ear size and the consequent measurements. Measuring the ear height along the long axis and the width at right angles to that, the ear varies in height from 5.5 to 7.5 cm and in width from 3.0 to 4.5 cm (50% to 65% of the height).
- *Protrusion:* Although measurements and standards can be listed in both degrees and centimeters of protrusion, many surgeons find an actual centimeter measure most practical in the operating room. A measurement of 1.5 to 2.0 cm from the scalp to the anterior surface of the superior pole of the helix most commonly provides a visually correct degree of protrusion.^{1,2}

Optimal aesthetic reconstruction of all congenital auricular deformities is based on a clear understanding of both the cartilage and soft tissue anatomy of a normal ear and a deformed ear and on an appreciation of the skeletal asymmetries that often coexist with these deformities. Although it may be obvious that there is an association between microtia and hemifacial microsomia, the effects of other skeletal anomalies (that is, positional, nonsynostotic plagiocephaly) on the position and prominence of an ear may be considerably more subtle. A reconstructed ear must not only be the correct size and shape but also bear the correct relationship to other facial features. The relationship between ear position and conformation of the underlying skeletal supporting structures is an important theme in the discussion of both prominent ears and the reconstruc-

Fig. 32-1 A, The normal ear and its parts. B, The ear's critical proportions.

tion of microtia.^{6,7} One must also be aware that variations in cranial vault shape may influence ear position and prominence, and this may throw off standard measurements. I am convinced that one should correct ear protrusion to what looks right rather than to a specific centimeter measurement.

TIMING OF SURGERY

There are three main considerations for determining the optimal timing for reconstructive procedures of the ear:

1. Psychological—timing the reconstruction to avoid undue psychological trauma from the deformity
2. Anatomic—taking into consideration the size of the contralateral ear in unilateral deformities and the strength of the available auricular donor cartilage in both unilateral and bilateral reconstructions
3. Growth—considering the growth of both of the ears in general and the growth of the ear after reconstructive procedures

Adamson et al⁵ reviewed the growth patterns of the external ear and concluded that (1) the ear reaches 85% of its adult size by the time a child is 3 years of age, (2) growth continues until adulthood, but little change in width or distance from the ear to the scalp occurs after 10 years of age, and (3) for all practical purposes, the normal ear is almost fully developed by 6 years of age. Farkas^{8,9} differed somewhat in his measurements, stating that the ear reaches 85% of full size by 8 years of age, 90% by 9 years, and 95% by 14 years. Work in the 1980s clearly showed that there is continued ear growth in adulthood, although conchal width does not change appreciably. This is something we intuitively recognize in viewing many elderly adults. This may play a factor in

deciding on whether to reduce the ear size when applying the varied otoplasty techniques that we will discuss with the adult patient.

I have had enough experience with unusual cases, in which I felt correction before 5 years of age was appropriate, to comfortably state that early surgery does not affect the long-term growth of the ear. However, there are practical considerations that argue against routine early intervention. Few if any children express concern about the abnormal appearance of their ears before reaching 5 or 6 years of age, even when the deformity is significant enough to elicit comments from their peers.^{10,11} The proportionally greater growth of the ear in these early years in relation to the rest of the facial features may in fact accentuate the prominence of the ear. Correction before this age, although quite possibly easing parental concerns about the child's appearance, may complicate the postoperative course if the child, even if not intentionally, pulls off the bandages and potentially disrupts the repair. Nevertheless, I have seen children who were clearly aware of their appearance by 4 years of age and were bothered enough that they both eagerly anticipated surgery and cooperated totally during the healing period.

Regarding the more complex nonmicrotia deformities such as group II and III constricted ears, Stahl's ear, and some cryptotias, surgery may need to be delayed until the conchal cartilage used for "expanding" the auricular framework is sturdy enough to support the changed skin envelope. This is certainly the case by 5 or 6 years of age. There are occasional group II constricted ears where unfolding the vestige along with posterosuperior reposition may help both with hygiene of the canal and masking of the more significant deformity until the age where the greater part of the reconstruction or otoplasty can be accomplished; however, this is more of an issue in microtia cases associated with significant displacement of the vestige because of underlying skeletal asymmetry.

PERIOPERATIVE CONSIDERATIONS

There are several perioperative considerations, such as prophylactic antibiotics, surgical preparation, and draping techniques, that should be discussed briefly here before proceeding with the specifics of the different ear deformities. There is considerable variation as to how each of these considerations is addressed from one surgeon to another, so these are included among a selection of several approaches.

Prophylactic antibiotics are recommended for most aesthetic and reconstructive procedures of the ear. For most surgeons, the risk of chondritis, the most feared complication of otoplasty, is a sufficient indication that at least an intraoperative dose of a broad-spectrum antibiotic should be given, and most surgeons also prescribe a similar oral agent for the first few postoperative days. Few surgeons allow sufficient time to thoroughly prepare the auditory meatus and canal with Betadine or a similar iodinated preparation (a routine strongly advocated by Brent¹²), even though this might be sufficient enough to eliminate the risk of chondritis. In my view, active ear drainage is a contraindication to all surgery on patients with nonmicrotia deformities. However, if a child has had myringotomy and tube placement and has some typical drainage, this is not necessarily also a contraindication.

Surgical draping is also subject to considerable variation based on each surgeon's preference. I prefer a standard head drape with staples to hold the drapes in place, which allows a full view of the face and both ears. This exposure is particularly important in patients with significant asymmetries. In addition to the head drape, two halves of a medium piece of Tegaderm cut lengthwise provide an excellent barrier to keep sideburn hair and postauricular hair out of the surgical field. Another alternative is using a single larger piece of Tegaderm over the whole area surrounding the ear, with a hole cut out for the ear.

RECONSTRUCTIVE TECHNIQUES FOR CONGENITAL NONMICROTIA AURICULAR DEFORMITIES

Prominent Ears

Anatomy and Goals of Otoplasty

The prominent ear is traditionally characterized by two major elements but is also influenced by additional factors. First, there is usually some degree of effacement of the antihelical fold, with an increased scapha-conchal angle causing increased projection of the superior pole of the ear. Second, the majority of cases show some degree of hypertrophy of the concha, which results in displacement of the entire ear structure from the side of the head. Ear position is also influenced by the shape of the skull. If there is preexisting plagiocephaly, asymmetry between the ears can be accentuated by the steeper underlying skeletal plane on one side compared with the other. In addition, upper pole prominence is accentuated in patients with a heart-shaped face in which there is a broader intertemporal distance than in an individual with a narrow face and mandible. The technique for correction of ear prominence needs to respect the effect of the underlying skeletal plane on both the upper and lower poles of the ear to ensure complete correction of the deformity. Without a degree of overcorrection of the upper pole, the end result may appear undercorrected. Techniques need to be further modified to correct macrotia and overgrowth of the lobule.

The most important factor in the correction of prominent ears, as well as the more complex deformities mentioned in this chapter, is correct analysis of the deformity and recognition that quite different factors may be at play on each side (Fig. 32-2). Most otoplasties will include some

Fig. 32-2 Variations in anatomy and causes of ear prominence. **A**, Significant prominence resulting from near-total effacement of the antihelical folds (with a suggestion of macrotia). **B**, Prominence resulting from conchal hypertrophy. **C**, Prominence in association with hypoplasia of the underlying craniofacial skeleton. **D**, The critical angle of cartilage between the conchal floor and antihelix influences the prominence of the lobule.

reduction of the concha, correction of the effaced antihelical fold, and additional elements, from reduction of ear size to the contour of the helical rim, antihelix, and lobule. Again, although normal ear proportions have been well documented, the recognition of abnormal size and projection is so innate that one's sense of normal is a much better guide in otoplasty than actual measurements.

Antihelical Fold

Effacement or deficiency of the antihelical fold ranks first in most discussions of the prominent ear.¹³⁻¹⁷ This deformity presents as a spectrum ranging from a totally indistinguishable antihelix with a confluent concavity from the antihelix to the scapha and the helical rim projected outward and forward, to a loss of definition of only the superior antihelix with prominence of the upper pole of the ear.

Conchal Size and Shape

Although less attention has been given to the importance of the concha in overall shape and projection of the ear,^{7,18,19} it makes sense, when thinking about the three-tiered configuration of the auricular cartilage framework, that the delicate antihelix and helical complex are mounted on the sturdier concha so that changes in conchal size and shape profoundly influence the overlying tiers. In my experience, it is rare to see ear prominence that does not have a conchal element.

There appear to be three ways in which the concha affects the prominence of the ear (Fig. 32-3):

1. Overall enlargement of the concha projects the ear away from the mastoid surface.
2. An extension of the helical crus across the concha creates a firm cartilage bar that pushes the ear outward.
3. The effect of the cartilage angulation at the junction between the cavum concha and the sweep of cartilage up to the antitragal prominence affects the position and prominence of the lobule and lower third of the ear.

The first element is well recognized. Little attention has been given to the second element, but once it is seen, it is easy to understand. The third element, once recognized, opens the door for understanding the approach to the isolated lower pole and lobule prominence.

Fig. 32-3 Combined otoplasty technique. **A** and **B**, Two views of the conchal incision.

Fig. 32-3, cont'd C-F, Start of the procedure with a conchal incision through the skin and cartilage; dissection continues in the loose plane behind the concha. Gentle pressure is applied to the concha, and the excess skin and cartilage is excised. G and H, The conchal cartilage is reapproximated with nylon sutures, and the skin is repaired with absorbable chromic sutures.

Continued

Fig. 32-3, cont'd I and J, The squid-shaped skin excision is followed by exposure of the perichondrium on the postauricular surface. The straight Keith needle marks the position for placing scapha to mastoid, helical sulcus to mastoid, and additional sutures, and these sutures are tied to adjust prominence. K and L, The final position of the lobule is set with placement of the first closing suture between point A' and points A, B, or C. The different positions of the sutures will vary the shape of the lobule as illustrated.

The third element of conchal shape, although it is not the only cause of lobule prominence, appears to play a key role. As the cartilage angle between the concha cavum and the antitragus becomes more acute (that is, as the antitragus tips closer toward the concha), this supporting structure projects the lower third of the ear and lobule outward. I think that this feature has a greater influence on the lobule position than the commonly described helical tail.

Anatomy of the Underlying Skeleton

Little attention has been given to the effect of the underlying skeleton on ear prominence, but it should be recognized and taken into account when planning the correction of prominent ears. The external ear is mounted on the bony base of the underlying temporal bone. Anomalies in skeletal shape and skeletal asymmetries can affect one or both ears. Perhaps the most recognizable example of this relationship is the change in ear position and projection in association with positional, nonsynostotic plagiocephaly. With the parallelogram deformation of the cranial vault, the ear on the side of occipital flattening is projected forward and is often more prominent.

A less subtle example of the influence of the skeleton on ear position is the effect of deficient temporal bone and medial positioning of the temporomandibular joint in hemifacial microsomia. In severely affected cases, without microtia, the normal ear may seem to be “sheared off the head,” with the upper half of the ear projecting outward and the lower half canted medially toward the hypoplastic face (see Fig. 32-2, C). Another example that shows some similarities is those patients whose general craniofacial shape includes a relatively broad head with a narrow face and mandible. Seen from the front, the face and head have a heart-shaped configuration. This slope from head to face may project the upper ear outward, creating ear prominence but showing otherwise normal and proportional ear features.

Although otoplasty techniques vary from one case to another, the overall goals of otoplasty remain the same¹³:

- Correction of protrusion (particularly the upper pole)
- Visibility of the helix and antihelix
- Smooth antihelical line
- Undisturbed postauricular sulcus
- Avoidance of a “plastered-down” look
- Avoidance of a sharp antihelical fold

Correction of a Prominent Ear

A review of all or even most otoplasty techniques is beyond the scope of this chapter. I will instead attempt to review the techniques that have been emphasized most often in the literature for correcting the typical prominence caused by insufficient formation of the antihelical fold and those cases resulting from conchal hypertrophy. Techniques must be varied when both elements of prominence require treatment and when overall reduction in ear size is also required. After a brief overview, I will discuss the approach that has evolved over my more than three decades of ear surgery. This approach has the greatest flexibility for correction of prominence in the full spectrum of nonmicrotia ear deformities and how the correct sequence of these procedures will lead those less familiar with this surgery to a significantly better understanding of the problem and how even subtle deformities can be corrected with high certainty of success.

Creating the Antihelical Fold

A review of both the plastic surgery and otolaryngology literature reveals a multitude of techniques for correction of the antihelical fold.^{13,15-22} In general, these techniques can be grouped into those that score or abrade the cartilage to control the direction and extent of folding and

those that rely on suture fixation of the cartilage.¹⁸⁻²⁰ In addition, there are a number of procedures that combine these techniques.^{6,7,20,21}

The cartilage-scoring techniques vary, based on whether the cartilage is simply scored²⁰ or actually cut through,²² and when it is scored, whether the scoring is on the anterior or the posterior surface of the cartilage. Although any of these techniques can be successfully accomplished by skilled hands, the risk of a sharp antihelical fold is considerably higher when a full-thickness cut is used in the body of the antihelical cartilage. Keeping in mind the potential dissatisfaction most patients will express when the cartilage shows surface irregularities and sharp, unnatural folds, I think that scoring techniques should be relegated to the history books—particularly given the fact that other techniques are available that easily avoid this problem, and all degrees of effacement can be corrected without the need of any disruption of the smooth surface of the antihelix.

Conchal Reduction

Some degree of conchal hypertrophy is present in virtually all cases of ear prominence, although certainly it is less significant in some cases. In my experience the largest number of patients who are dissatisfied with the results of a previous otoplasty focus on the overaccentuation of the antihelical fold to correct prominence when conchal hypertrophy has been missed or ignored as an important element of their initial prominence.^{7,21}

The techniques for correcting conchal hypertrophy, once properly identified, include lowering the concha by creating a new antihelical fold, conchal setback with conchal mastoid sutures, and conchal reduction.^{7,15,21} The reduction procedures can be divided into those that excise cartilage alone (usually through a posterior approach) and those that resect both cartilage and skin through an anterior approach. Although minor degrees of conchal prominence are handled through the creation of a new antihelical fold or by using a conchal mastoid suture, I think that most patients with significant degrees of conchal hypertrophy require cartilage excision.^{7,21}

The choice of a posterior or anterior approach to the cartilage excision is, for the most part, one of personal preference; either approach is effective, and a surgeon gains facility with the approach used most frequently. In my opinion, there is considerably more control with an anterior approach than a posterior one, and in cases where the resection will be 0.5 cm or more in width, the extra skin left from the use of a posterior approach may not shrink down sufficiently to avoid leaving a visible fold in the conchal floor. This fold may be more visible than a fine anterior conchal scar, which is rarely visible by 1 year after otoplasty. In cases in which a conchal incision is used to help break the spring of the antihelical body to allow smooth reshaping and no conchal resection is planned, the cartilage incision can be made from a posterior approach alone, although these cases are relatively few. With meticulous skin closure, the scar is rarely visible and in my many years of ear surgery both for correction of nonmicrotia deformities as well as harvest of composite conchal grafts, I have seen only a single patient with hypertrophic scarring in the concha (a CHARGE* syndrome patient).

Current Combined Otoplasty Approach

The evolution of my current technique was from early use of the technique described by Stark and Saunders,²⁰ which combined posterior thinning (dermabrasion) of the proposed antihelical fold and suture fixation, with very rare conchal reduction. In the cases where some degree of

*CHARGE stands for *coloboma*, *heart defect*, *atresia choanae* (also known as *choanal atresia*) *retarded growth and development*, *genital abnormality*, and *ear abnormality*.

conchal reduction was carried out, it was immediately evident that there was much better control of the folding of the antihelical fold and little or no need to thin the antihelical cartilage to get it to bend while the sutures were tied to guide the correction of the antihelical effacement. Even with careful posterior thinning of the antihelical cartilage, some irregularities were seen on the anterior surface. Combining these observations with those from a group of secondary otoplasty patients in whom the initial otoplasty surgeon clearly failed to recognize the significant conchal hypertrophy underlying their deformities and in compensation sharpened the antihelical fold to the point of losing all visibility of the helical rim, a technique centered on “remodeling” the concha seemed to be the best match for the anatomy.

Otoplasty with chondrocutaneous conchal resection as the cornerstone of correction, in combination with posterior suture shaping and fixation of the antihelical fold, avoids any thinning or potential irregularities in the antihelix that can occur with many of the cartilage-scoring techniques, and minimizes the risk of recurrence that may be seen with suture techniques alone. The integrity of the antihelical cartilage is maintained, because the perichondrium overlying both surfaces of the antihelix is left undisturbed, yet the cartilage spring is diminished as a result of the “break” at the conchal level.

With the exception of rare cases in which there is no visible conchal component to the deformity, the procedure begins with a conchal incision and excision of a crescent of cartilage with a smaller skin component (see Fig. 32-3, *A* through *H*). For lesser degrees of cartilage resection, no skin should be excised. After repair of the concha, attention is turned to the postauricular surface, where skin excision and exposure of the posterior perichondrium over the scapha, helical sulcus, and helical tail is followed by suture placement. Sutures are tied to correct prominence, and closure of the inferior incision sets the shape and correction of the lobule (see Fig. 32-3, *I* through *L*). With these steps completed, adjunctive procedures may be performed, such as correction of helical rim deformities, correction of excessive antitragus prominence, and additional reduction of lobule size. Although one may feel that the foregoing discussion of the shift in thinking about and approaching the prominent ear in general and concha specifically is time consuming, it is critical for surgeons to understand and correct the whole range of nonmicrotia deformities, both classic and rare.

Surgical Technique

Details of the procedure follow, but the preceding general sequence should be kept in mind. Although I have made every effort to describe the nuances of each step, the indications and benefits of each maneuver become apparent as one gains experience with the procedure and a better appreciation of the flexibility inherent in this approach. With the rare exceptions noted, the techniques used are similar for both children and adults.

With the patient under general anesthesia using a reverse-airway endotracheal tube (or under intravenous sedation), the face and both ears are sterilized with a green soap solution and subsequently draped with a standard head drape. Stray hairs are secured with Tegaderm or some other clear, sterile drape. A solution of 0.5% lidocaine with 1:200,000 epinephrine is infiltrated into the anterior and posterior surfaces of both ears. Bilateral great auricular nerve blocks with 0.25% bupivacaine are also injected for postoperative analgesia. A broad-spectrum antibiotic is administered through an intravenous line.

The procedure typically begins on the more prominent side, with the incision on the anterior surface of the concha. The incision is placed at the junction of the posterior conchal wall and the floor of the concha (see Fig. 32-3, *A* through *C*), beginning in the cymba concha and continuing along the cavum concha to a point below the antitragus but not as far as the external auditory

meatus. This incision is deeper in the concha than the incision described by Elliott.¹⁵ Placing the incision too high in the concha decreases control of the antihelical fold, allowing the cut edge adjacent to the antihelix to spring forward when the antihelix is shaped. The incision is carried through both the anterior skin and conchal cartilage, stopping shy of the posterior conchal skin. Sharp dissection in the loose areolar plane behind the concha (not in the subperichondrial plane) frees soft tissue and skin from the posterior surface of the conchal bowl (see Fig. 32-3, *D*). A gentle setback of the antihelix with finger pressure accurately estimates the degree of conchal hypertrophy and the amount of cartilage and skin resection needed to create an aesthetically pleasing position for the ear (see Fig. 32-3, *E*).

Usually a crescent-shaped chondrocutaneous segment is excised (see Fig. 32-3, *C* and *F*). To ensure a tension-free closure, more cartilage is typically resected than skin, particularly along the inferior concha deep to the antitragus (where excessive resection can pull the antitragus upward and increase the prominence of the lower pole of the ear and lobe). The edges of the conchal cartilage are approximated with three or four interrupted 5-0 clear nylon sutures (see Fig. 32-3, *G*). How the inferiormost suture is placed at the junction of the cavum concha and antitragus adjusts the angle between these landmarks and strongly influences the cartilage support to the lobule. A slight overlap of cartilage (antitragal segment over conchal segment) tips the lobule posteriorly. Once the cartilage is repaired, the anterior skin is closed with a combination of 5-0 chromic gut with horizontal mattress sutures, followed by a running 6-0 mild (fast-absorbing) chromic gut suture (see Fig. 32-3, *G* and *H*). With these maneuvers completed, the helical rim and ear might seem more prominent at first, but gentle pressure again applied to the antihelix demonstrates a relaxing of the tension needed to bend the antihelix back for its desired correction.

Correction of an effaced antihelix and prominence of the lobule begins with a retroauricular squid-shaped skin excision down to the perichondrium. The squid-shaped excision (which, in essence, is the typical dumbbell-shaped ellipse with the inferior end widened to a diamond shape) is designed to allow access to the posterior surface of the scapha and helical sulcus for suture placement and to assist in correction of the lower pole prominence. The diamond-shaped inferior extension of the squid is positioned with its maximal width at the point of maximal lobule prominence (see Fig. 32-3, *I*). Exposure of the posterior surface of the conchal bowl and scapha is achieved without dissection of any perichondrium off the cartilage.

Preserving the perichondrium is essential to lessen the possibility of subsequent sutures pulling through the cartilage. As the dissection proceeds to expose the posterior surface of the cartilage, care is taken when dissecting the area of the helical sulcus to identify the helical tail. The latter is seen as a duplication of cartilage extending inferiorly from the middle to lower third of the helical rim. This dissection must not free the cartilage of the tail from the skin overlying its anterior surface, because this would diminish the effectiveness of the correction of lobular prominence. The final dissection proceeds onto the mastoid and temporal surfaces, freeing the soft tissues sufficiently to ensure that later sutures can be securely placed into the fascia rather than more mobile overlying tissue. Bipolar cautery is used throughout this process to ensure hemostasis.

Before the sutures are placed to further correct ear prominence, pressure on the helical rim and antihelix again demonstrate that the spring or resistance of the cartilage to further antihelix shaping is significantly decreased, and the reshaping can be accomplished without any sharpening of the antihelix. This is a key point of this otoplasty technique, because even a limited amount of conchal resection will result in this lessened spring and increased ease of shaping of the antihelix. With the current exposure of the posterior surface of the concha, additional sutures can

be placed before the key posterior shaping sutures if they are needed to complete an accurate closure of the conchal defect.

Two or three 4-0 clear nylon sutures are placed from scaphal cartilage and helical sulcus cartilage to mastoid fascia to correct the prominence of the upper and middle thirds of the ear. The third, most superior, suture may be placed from the region of the triangular fossa to the temporal fascia. The proper placement of these permanent sutures is determined by applying pressure to the desired points on the anterior surface of the ear with a straight Keith needle, then passing the point of the needle through the selected spot so it can be viewed on the posterior surface of the cartilage (see Fig. 32-3, *I* and *J*). The nylon suture is then placed at each specific point without needing to tattoo the cartilage. As the suture is placed, the Keith needle is withdrawn. The sutures are then passed through mastoid or temporal fascia. Once all of the sutures are placed, they are tied, beginning with the scaphal suture, to the proper tension to create a smooth antihelical fold. Before cutting each suture, a forceps is used to grasp the knot and slide it down against the mastoid surface, minimizing any risk of later extrusion of sutures. As these sutures are tied, care should be taken to observe the relationship of the reshaped antihelix and the helical rim to ensure that the helical rim remains visible from the frontal view. The suture from the triangular fossa to the temporal fascia creates a more natural line from the upper pole of the ear to the helical root. Again, the exact suture position and closing tension is easy to control, and subtle differences can be easily observed.

Once the upper and middle auricular prominences are corrected, the lobule position is addressed by closing the posterior squid-shaped defect with 5-0 chromic gut. With the diamond-shaped inferior portion of the squid design previously described, the appropriate contour, shape, and projection of the lobule are created by varying the initial suture position, with *A'* (the point of the diamond at the point of maximal lobule prominence) being sutured to *A*, *B*, or *C* (more frequently to *A* rather than to *B* or *C*) (see Fig. 32-3, *K* and *L*). Once this initial suture is placed, the remaining closure is accomplished with a running 5-0 chromic suture. Correction of the more prominent side first allows for a symmetrical “setback” by providing a guide for placing the sutures that define the antihelix and lobule prominence (Figs. 32-4 and 32-5). Finally, as one becomes more comfortable directly approaching minor cartilage irregularities or areas of residual prominence, such as an antitragus or a Darwin’s tubercle, one can directly resect the area of cartilage prominence through a small additional incision along the border of the area of cartilage to be trimmed and repair the skin with 6-0 chromic suture. These additional incisions are virtually invisible when healed, and this type of approach is very much a part of correcting many of the other nonmicrotia deformities.

Macrotia

The approach to prominent ears, as previously discussed, must be flexible and adjusted to the unique features of each deformity. Cases of true macrotia require reduction of the overall ear size in addition to correcting ear prominence. In general, reducing the vertical height of the ear is most easily accomplished by using an excision at the junction of the middle and lower thirds of the ear in conjunction with a helical rim advancement using a posteriorly based chondrocutaneous flap. The excess cartilage is excised from the scaphal region, the rim is advanced along, and additional excess skin and cartilage are excised just inferior to the helical tail. This approach affords an excellent view for either further development of the antihelical fold or additional conchal reduction.

Fig. 32-4 A-D, Preoperative views of a 7-year-old girl with prominent ears caused by mild conchal hypertrophy, in combination with asymmetrical effacement of the upper antihelical folds. E-H, Results 6 months after the combined otoplasty approach was used. Note the excellent correction with smooth antihelical folds and the natural visibility of the helical rim in the anterior view.

Fig. 32-5 A-D, Preoperative views of a 5-year-old girl with prominent ears caused by conchal hypertrophy and mild effacement of the antihelical folds (left to right). E-H, Results at 6 months postoperatively. Note the lack of distortion of the postauricular sulcus.

Constricted Ears

Anatomy

A constricted ear was previously described in the literature using a broad range of confusing terms such as *cup ear* and *lop ear*. The terminology for this group of congenital ear deformities was simplified by Tanzer,²³ who classified this entire group of anomalies as *constricted ear*. Tanzer²³ further divided constricted ear types based on both the degree of cartilage deformity and the extent of skin deficiency. Group I deformities are minor, involving the helix alone and giving a lidded appearance to the ear. Group II deformities are moderate to severe, involving the helix and scapha, and are further subdivided into group IIA without skin deficiency and group IIB, which requires supplementation of skin at the margin of the auricle. Group III deformities have extreme cupping with a tubular form to the ear, with great similarity to a large chondral remnant type of microtic deformity (Fig. 32-6). Group III deformities are often associated with deformities of the external auditory canal and middle ear.

Cosman²⁴ described four fundamental aspects of the constricted ear deformity that vary depending on its severity: (1) lidding, (2) protrusion, (3) decreased ear size, and (4) low ear position. These features correlate quite well with Tanzer's groupings.²³ *Lidding* is caused by helical overhang, arch shortening, and flattening of the antihelical crura. It may be further accentuated by a crimping of the rim with adhesion to the scapha. Decreased ear size is the result of the previously described changes in addition to a decreased skin envelope, conchal widening and angulation, and an actual decrease in the overall size of the cartilage. A low ear position is not unlike that seen in a variety of severe auricular malformations and is sometimes related to other associated skeletal deformities and syndrome-related anomalies.

Fig. 32-6 Constricted ear deformities are grouped on the basis of the degree of lidding, the decreased ear size as the radius of the curve of the helical rim decreases, and the degree of skin shortage. **A**, Group I, with lidding alone. **B**, Group IIA, with combined lidding and increased constriction of the helical rim, but without significant skin shortage. **C**, Group IIB, with greater constriction and skin shortage. **D**, Group III, with skin and cartilage deficiency comparable to a large conchal remnant microtia.

Treatment Guidelines for the Constricted Ear

Because the presentation and spectrum of constricted ears are so variable, the treatment must be individualized to the specific deformity. Regardless of the technique chosen, the specific aims of treatment are to establish maximum (or near-normal) vertical height to the ear and to correct the ear prominence.²⁵ Techniques vary in their ability to increase the vertical height through cartilage reshaping alone, or in combination with additional contralateral auricular cartilage grafts or a costal cartilage graft. Before looking at the approach that we now use, which is equally applicable to most of the other nonmicrotia deformities (constricted ear, cryptotia, Stahl's ear, and a group of atypical unnamed deformities), it is worthwhile reviewing the techniques historically applied to the constricted ear.

One consistent shortfall for the majority of techniques described in the literature is that few techniques are capable of establishing a normal vertical ear dimension.^{23,25,26} In fact, a careful review of the 17 techniques illustrated in Cosman's excellent paper on the constricted ear²⁴ reveals that only one technique accomplishes this normal vertical ear dimension. In cases of bilateral constriction, obtaining symmetry between the two sides may not be a problem, but when the contralateral ear is of normal size, one must either accept that there will be a discrepancy between the two sides, or as suggested by Brent,¹² the size of the normal ear must be reduced to match the reconstructed side.

With this in mind, the key elements in correction of the constricted ear are:

1. Placement of the incision along the line of the future corrected helical rim
2. Full visualization of the constricted cartilage of the upper half of the ear
3. Release of all adhesions in the cartilage
4. Expansion of the cartilage with conchal cartilage grafts
5. Redraping of the anterior skin flap over the reshaped cartilage of the upper pole of the ear

With the incision moved to an anterior position, the skin envelope can redrape in a way that was not possible with the previously accepted posterior incision, and allows the skin to accommodate a considerable increase in the size of the upper pole. Although early experience with this approach will raise concerns about the ability to accomplish this "expansion" of the ear while maintaining a healthy vascular supply to the anterior skin flap, meticulous dissection of the cartilage in the subperichondrial plane will leave a healthy vascular flap. The redraping is further assisted by multiple fine quilting sutures to see that there is no tenting of the skin as it redrapes. These principles follow through all cases of constricted ear, although in varying degrees, as we will see when looking at each of the deformities.

Group I Constriction

Treatment of group I constriction is directed at two elements: the lid of extra skin and cartilage and the prominence of the upper pole. In fact, it is not uncommon to find an element of this type of constriction with many of the more typical prominent ears. More recent experience has demonstrated that in both group I and group II constrictions, there is often a degree of crimping of the helical rim (in addition to the lid) where there is an acute angulation between the helical rim and scaphal cartilage. Often the flattened rim is adherent to the scapha, with an apparent deficiency of skin in the area of adherence. Treatment is similar with either presentation and the maneuvers required will apply equally well to the crimping and distortion of cartilage in the upper pole in cases of cryptotia and Stahl's ear.

In our experience, it is rare that trimming of the lid alone will give an optimal result. Even with the release of any fibrous adhesions, the superior helical rim may still not unfold to its maximum height, and without support of the released cartilage with a “batten” of cartilage graft, it will still tend to droop. Once the graft supports the upper pole, the skin is redraped using multiple 6-0 chromic sutures to “quilt” the skin into the contours of the reshaped cartilage and prevent tenting of the skin, and the helical rim incision is closed.

In the procedure illustrated, the lid or hood of extra tissue is outlined along the line of the planned helical rim (Fig. 32-7, *A* and *B*). The excess tissue is trimmed and the rim repaired (Fig. 32-7, *C* and *D*). If the upper pole is also prominent, an ellipse of skin can be excised from the postauricular surface in the upper sulcus, and a suture or sutures (4-0 clear nylon) can be placed from the scaphal area to the mastoid and tied to correct this prominence. If there is concern about

Fig. 32-7 Correction of lidding in group I deformity. **A**, The deformity. **B**, The incision is planned along the proposed new border of the helical rim, and the skin flap of the lid is dissected free to view the excess cartilage, which is trimmed. **C**, The skin flap is redraped, and the excess is excised. (As shown, the flap is split first, then the excess is trimmed after placing the central suture.) **D**, The helical rim incision is closed. Also shown is the conchal incision that was used to correct the associated ear prominence. **E**, At the completion of the procedure, the incision now lies along the border of the helix. Multiple quilting sutures can be used to ensure that the skin redrapes without tenting.

the vascular supply to the intervening flap that arises with a wide posterior skin excision, an alternative approach is to place a single incision at the auriculocephalic angle and tunnel the suture down from the anterior incision through to the sulcus. The scaphomastoid sutures can then be passed through these incisions without concern for the vascular supply. The postauricular skin closure is carried out in a similar fashion to that described for prominent ears, and the helical rim is repaired using 6-0 mild (fast-absorbing) chromic sutures (Fig. 32-7, E).

Group II Constriction

Although historically group II constricted ears have been separated into groups IIA and IIB based on the degree of skin deficiency, in all practicality, all group II deformities have some degree of skin deficiency. It has been our experience that the correction of group II constrictions, with increasing degrees of constriction of the skin and cartilage, presents perhaps the greatest challenge in ear reconstruction surgery. At the point when they are better classified as large conchal remnant microtia,²⁷ the approach is simplified through an expected staged reconstruction with lateral augmentation of the skin envelope in second-stage reconstruction. Although degloving the ear and expanding the cartilage with banner flaps²³ or upward and outward advancement of the cartilage of the cavum concha carried on the helical crus is capable of unrolling the constriction,²⁵ the newly enlarged ear frequently lacks strong vertical cartilaginous support. Once the skin is redraped over the cartilage, some of the height is lost. The addition of a conchal cartilage graft (ipsilateral, contralateral, or both) is frequently necessary to improve and strengthen the vertical correction; however, without the addition of skin, usually in the middle third of the ear, even the extra skeletal support may be inadequate. The cartilage harvest in each is readily accomplished as part of correcting the inherent prominence of these deformities as well.

Again, years of experience have led to the realization that degloving the upper pole of the ear beginning with a posterior incision may not only increase the risk of vascular compromise when the skin is dissected extensively onto the anterior suture, but also and more importantly, the redraping of the skin is more limited, because the constricted skin cannot fully splay out over the new framework. Approaching the deformity through an incision along the planned new helical rim allows the anterior skin to better adapt to the new shape without tethering and pulling down on the new upper pole framework. This approach allows one to gain significantly great vertical height without the need for additional posterior skin flaps. For symmetrical group IIA deformities, the upper pole corrections can be used as an adjunct to the previously described combined otoplasty techniques with excellent correction (Fig. 32-8).

For the benefit of comparing varied approaches, we have in the past successfully reconstructed some group IIB deformities with the addition of posterior skin flaps. The technique illustrated in Fig. 32-9 is similar to one described by Kislov²⁶ in that the constricted ear is split in its middle third, allowing the ear to open to a normal vertical dimension with a postauricular flap to cover the defect. A crescent-shaped chondrocutaneous flap from the concha (see Fig. 32-9, C and D) aids in the correction of the ear prominence and provides the needed tissue.²⁸ However, the Kislov approach²⁶ and variations of it have the downside of leaving transverse-oriented scars in the lower antihelix where the flap is spliced into place, and the result still does not have the flexibility achieved with the additional skin and cartilage added to the constricted upper pole of the ear that can be gained with altered placement of the incision, upper pole cartilage restructuring and a graft, and redraping of the skin (Figs. 32-10 and 32-11). If the deformity is unilateral and additional cartilage is needed, it can be harvested from both the ipsilateral and contralateral ears, but in most cases of bilateral constriction, the technique shown in Figs. 32-10 and 32-11 can yield near-normal height and superior shape.

Text continued on p. 964

Fig. 32-8 Correction of group IIA constriction in a patient with symmetrical constriction bilaterally. **A-D**, Preoperative views show ear prominence, decreased ear size, and lidding. **E-H**, Results 1½ years postoperatively. Correction was accomplished using a combination of maneuvers to correct lidding and the previously described combined otoplasty technique.

Fig. 32-9 Correction of group IIB constriction with flaps similar to the technique described by Kislov, but using a chondrocutaneous flap rather than a graft to fill the defect. **A**, Preoperative view. **B** and **C**, The planned incisions are marked. **D**, A chondrocutaneous flap is fitted into the defect created by splitting the constricted rim. Also shown is the postauricular skin flap that will wrap forward over the helical rim to join the edge of the chondrocutaneous flap. **E** and **F**, The corrected constriction approximately 1 year postoperatively.

Fig. 32-10 Correction of group IIB constriction. **A-C**, This child, seen at surgery, had asymmetrical constriction with the more significant deformity of the left ear, which shows a constricted scapha, lid-ding, prominence, and skin deficiency. **D** and **E**, The upper pole of the cartilage was approached anteriorly through an incision along the proposed future helical rim and the constricted, fully exposed cartilage. **F-H**, The cartilage lid was trimmed after exposure and set aside as additional graft material, and the upper pole was released or split in a manner to provide the best contour to the upper pole. In each case, the scapha was released with incisions planned to allow the most stable repositioning and fixation of the segments to the graft. Here it was split transversely until the constricted upper pole opened out.

Fig. 32-10, cont'd I-L, The cut segments of the scapha were overlapped or spliced together and combined with the conchal cartilage graft. The resected segment of the helical rim lid was used to fill the residual rim defect after first setting the projection of the helical rim lid with supporting scapha to the mastoid and triangular fossa to the temporal fascial sutures. The skin was redraped with multiple quilting sutures, ensuring that there was no tenting of the skin over the cartilage contours, and the helical rim incision was closed. M, The correction is seen 2 weeks postoperatively.

Fig. 32-11 Correction of asymmetrical deformities with prominence, constriction, and acute crimping of the helical rim using a similar approach to that in Fig. 32-10. The patient is seen preoperatively (A and B) and 3 months postoperatively (C and D).

The grafts to the upper pole of the ear are spliced into place with 5-0 and 6-0 clear nylon sutures, placing the sutures in such a manner as to secure the adjacent overlapping cartilage edges for a smooth transition. Once the primary grafts are in place and the greater part of the grafting is completed, some supporting sutures of 4-0 clear nylon are placed in a similar fashion to those used in the typical correction of the prominent ear. These sutures set the projection of the upper pole (sutures from scapha, concha, and triangular fossa to the mastoid and temporal fascia). Once this is accomplished, the final trimming of the helical rim or an additional graft can be placed. (Typically a remnant of the original lid may be needed at the junction of the upper pole and midhelical rim for a smooth transition when seen in frontal view.) Not uncommonly, in bilateral cases in which there is limited available additional conchal cartilage, the thin rim of the original lid is available for this final graft.

An additional point that is pertinent to the treatment of constricted ears, as well as the remaining upper pole deformities, relates to the harvest of cartilage. In each of these cases, the harvest of the conchal graft aids in correction of the ear prominence associated with many of these deformities. Depending on how much graft is harvested, the conchal cartilage edges may not be approximated, and there will be a conchal defect, as in any case where a large conchal graft

has been harvested in other reconstructive procedures. The cartilage defect will not be visible if the skin is closed without tension and the overall shape of the antihelix has not been disrupted.

Group III Constriction

In most cases the treatment for group III constriction is the same as the treatment for the so-called *conchal-type microtic remnant*.²⁷ There is a severe deficiency of both cartilage and skin, and reconstruction typically requires placing a costal cartilage framework, which is spliced into the usable parts of the constricted cartilage remnant. Following the skin flap design of Firmin²⁹ may provide the best use of the skin flaps. The reconstruction, similar to that for microtia, generally requires two or three surgical procedures to fully splice the parts together and complete the elevation of the helical rim and create the postauricular sulcus. With increased experience with the techniques described for the treatment of group IIB constrictions, unilateral cases of group III constrictions with a large conchal remnant may be well reconstructed using combined ipsilateral and bilateral grafts and auricular flaps without the need for costal cartilage. With this approach, the final result will have finer cartilage detail and a more naturally flexible ear, but the height may be slightly shorter than that gained with placement of a costal cartilage graft. The reconstruction may also require a second surgery.

CRYPTOTIA AND STAHL'S EAR

A number of congenital ear deformities, in addition to those described previously, involve varied deformation of the antihelix and upper pole of the auricle. Although these deformities are not common in whites or other races in the United States, they are seen with fairly high frequency in the Asian population (cryptotia occurs in approximately 1 in 400 to 500 Asian births).³⁰ Because these deformities are relatively rare, most surgeons have limited experience treating them, and although an in-depth discussion of each is beyond the scope of this chapter, I think it is worthwhile to review their anatomy and make several key points concerning their evaluation and treatment. The key point to understand in the correction of congenital ear deformities involving varied deformation of the antihelix and upper pole of the auricle, as well as the constricted ear deformities previously discussed, is that it would be much better to put many of the classifications and names aside and consider this entire group of ear deformities, and many other atypical unnamed defects, to be upper pole deformities. Each of these deformities has an element of deformation or deficiency of cartilage, in part because of fibrous adhesions, and a varied degree of skin shortage. Using the approach described earlier to visualize the cartilage and address the cartilage deformity, the reconstructions can be readily accomplished.

Cryptotia: Anatomy and Treatment

Cryptotia is characterized by failure of the upper pole of the ear to stand out from the head (Fig. 32-12). The three basic features of the deformity were described by Washio.³⁰ I have added a fourth feature that may need to be addressed for optimal outcome:

1. Buried superior pole of the auricle beneath the scalp skin
2. Scaphal underdevelopment
3. Sharpening of the antihelical crura, particularly the superior crus
4. Helical rim crimping and adhesion

Hirose et al³¹ thought that this deformity was the result of an anomaly of the intrinsic transverse and oblique auricular muscles. Based on this theory, these investigators divided cryptotia into type I (transverse muscle type), in which the body of the antihelix and the superior crus are compressed together, and type II (oblique muscle type), in which there is gross contraction of the body of the antihelix and an acutely bent inferior crus.

Treating cryptotia, regardless of the technique chosen, consists of releasing adhesions, reshaping cartilage, and creating the superior helical sulcus with a skin flap closure. According to Washio,³⁰ the most important element of the correction is the release of all adhesions on the posterior aspect of the antihelix (see Fig. 32-12, *E*), combined with reshaping the superior crus using suture fixation. Once the upper pole of the ear is projected away from the scalp, the posterior defect can be repaired using the basic principles of plastic surgery. Rotation flaps and V-Y advancement flaps have been used most commonly, advancing skin from inferiorly and posteriorly in the sulcus into the superior sulcus.³⁰⁻³² If the deformity includes a crimping and adhesion of the superior helical rim, this deformity should be addressed as well by releasing anterior adhesions and splinting the newly shaped helical rim with a batten graft of conchal cartilage (see Fig. 32-12, *F*). Although the greater part of the deformity can be completed without addressing the anterior crimp, and previous descriptions of the treatment of cryptotia have not included this added correction, the final outcome is more refined when the anterior deformity is also addressed.

Fig. 32-12 Anatomy and correction of cryptotia. **A** and **B**, Typical deformity of cryptotia shows the buried upper pole of the ear and distortion of the upper pole. The deformity is most commonly caused by acute folding of the superior crus resulting from posterior adhesions, and may also include crimping and distortion of the helical rim as a result of anterior adhesions.

Fig. 32-12, cont'd **C**, Incisions are designed to develop flaps to cover the superior helical rim and advance into the defect to create the superior sulcus. **D**, The superior pole of the ear is released from the scalp. **E**, All adhesions are released from the postauricular surface of the superior crus. **F**, The skin flap has been elevated to expose the anterior surface of the helical rim and scapha, allowing the release of adhesions and placement of a batten of cartilage (*arrow*) to splint the rim in its corrected position. **G** and **H**, The anterior flap is redraped over the corrected cartilage, tacking the skin flap into the cartilage with through-and-through fine chromic sutures, and the postauricular flap is advanced into the defect to line the sulcus. **I** and **J**, One month after correction, seen in close-up and wider views, showing the natural shape of the upper pole and the well-defined superior sulcus.

Stahl's Ear: Anatomy and Treatment

Stahl's ear, an unusual deformity that is sometimes referred to as *Spock's ear*, has as its main feature a third crus in combination with a flat helix and malformed scapha.³³ The third crus typically projects from the antihelix at almost a right angle outward toward the helical rim, and in some cases there is only a displaced superior crus and not three crura. This deformity forces the helical rim up into a point at the junction of the middle and upper poles of the auricle (Fig. 32-13, *A*). I think that there is also a group of congenital ear deformities in which there is just a vertical lengthening of the superior crus (without a third crus) that creates a similar distortion of the helical rim and pointing of the ear, and I consider this to be a variant of Stahl's ear (Fig. 32-13, *B*).

Historically, treatment of Stahl's ear has consisted of direct exposure of the malformed cartilage, cartilage Z-plasty or reversal, and cartilage suture techniques.³³⁻³⁵ However, none of these techniques has been consistently effective in fully correcting the deformity. Applying the approach described for the whole group of upper pole deformities, with direct visualization of the deformed cartilage, these deformities will effectively be corrected through direct release of the deformed cartilage, use of conchal cartilage graft, appropriately placed sutures to reshape the antihelix, and redraping of the skin (Figs. 32-14 and 32-15), as well as a whole host of deformities that defy specific description beyond noting the specific anatomic defects.

Fig. 32-13 *A*, Stahl's ear deformity has as its main feature a third crus in combination with a flat helix and malformed scapha. *B*, A group of deformities exists in which the upper pole is elongated by a long superior crus and elongated scapha that results in a pointed ear. I consider this group of deformities to be variants of Stahl's ear.

Fig. 32-14 Stahl's ear corrected with reshaping the upper pole through the direct approach and conchal cartilage graft in addition to correction of ear prominence on the contralateral side. **A-D**, Anterior and lateral views in wide and close-up preoperative images show the addition of crimping and adherence of the helical rim and third crus. The left ear is prominent. **E and F**, The patient is seen 10 years after correction of the prominence and helical rim deformity. The procedure involved the exposure of upper pole cartilage, release of adhesions, and conchal cartilage graft to support the reshaped helical rim.

Fig. 32-15 Correction of a variant of Stahl's ear. **A** and **B**, Frontal and posterior views of the pointed or Spocklike upper pole of the ears is evident. This is this reason that the patient sought correction. **C** and **D**, In lateral view, it can be seen that the origin of the deformity is not a typical third or displaced superior crus of a typical Stahl's ear, but rather an elongation of the superior crus and scapha pushing the helical rim upward. The deformity is slightly greater on the right side. **E-I**, The incision is placed along the helical rim, and the upper pole of the ear is fully skeletonized to allow full access to the cartilage.

Fig. 32-15, cont'd **J**, The anterior lid of extra cartilage is outlined and resected. **K-N**, The helical rim cartilage is freed and a portion resected, and then the shortened helical rim is fixed in place with sutures to the junction with the midthird of the helical rim and to the shortened scapha. **O**, The skin is redraped and the excess resected. **P** and **Q**, The completed correction is shown in comparison with the elongated preoperative shape; the ear has been shortened and has a more natural curve to the upper pole. **R** and **S**, Close-up views of the right and left ears after correction.

NONOPERATIVE TREATMENT OF CONGENITAL EAR DEFORMITIES

In addition to the surgical techniques previously described for the treatment of prominent ears, constricted ears, cryptotia, and Stahl's ear, each of these deformities may be treated and corrected at least partially by nonoperative splinting techniques. First described by Matsuo et al³⁶ and then by Brown et al,³⁷ the nonoperative approach is based on experimental evidence that auricular cartilage is soft and malleable during the neonatal period while maternal estrogen levels are still high. Once these levels drop (usually after 2 weeks of age), the cartilage becomes firmer and holds the shape into which it has been molded (Fig. 32-16).

This nonoperative approach has been applied most successfully to Stahl's ear, group I and II constrictions, and prominent ears when the primary feature is effacement of the antihelical fold. Although a variety of splinting materials and elaborate prefabricated splints have been used, I have found that lead-free solder with a covering silicone sleeve, taped on with Steri-Strips, is well tolerated and has never been associated with skin necrosis (a concern with harder splinting materials), and does not require the purchase of costly materials. Although Yotsuyanagi³⁸ has reported that splinting can be effective even in older children (6 years of age and older) with a thermoplastic splint applied for a relatively short period, this has not been substantiated by other investigators. It is my experience that effective nonoperative molding of the ear can be carried out until about 3 months of age. After that age, it is rare for the baby to leave the splint in place continuously, and rare for the parents to persist in replacing it. Deformities that do not involve significant skin shortage or sharp crimping of the cartilage and are associated with fibrous adhesions between cartilage surfaces are more amenable to nonoperative treatment.

Fig. 32-16 Nonoperative splinting in the neonatal period. **A**, A Stahl's ear deformity. **B**, The splinting material of lead-free solder and silicone tubing used for protective cover. **C**, The splint fitted to shape the ear from the helical sulcus to the triangular fossa. **D**, Another variety of rubber-coated wire with Steri-Strips holding the splint in place. **E**, The corrected deformity. **F** and **G**, A more complex deformity in a 2-week-old infant with features of both constriction and Stahl's ear. **H** and **I**, Six weeks after 5 weeks of splinting, with excellent correction.

When completing the splinting process, it is important for the parents to carefully observe the ear closely for 24 to 48 hours, because there may be some recurrence of the deformity that if monitored closely can be corrected through an additional week or two of splinting. In addition, it has been noted that of the varied deformities treated with nonoperative treatment, prominent ears are the least well corrected. This would seem to support the earlier discussion of the importance of the conchal size and projection being the underlying cause of most prominent ears. Splinting can quite effectively correct the effaced antihelical fold, but it has little or no benefit in correcting conchal shape.

CONCLUSION

The group of nonmicrotia ear deformities covers a broad spectrum of defects. Although some of these fall into well-recognized and named deformities, there are also many that defy naming and about which little has been written. If the deformities are separated based on the degree of prominence and whether or not the upper pole of the ear is deformed, it is possible to apply a systematic approach to their treatment that yields consistent natural results. The choice of otoplasty technique is not as important as picking the appropriate procedure for the specific deformity being treated. In addition, recognition that the otoplasty technique chosen must be tailored to the deformity, rather than the reverse, is critical to avoid an unfavorable result.

Chondrocutaneous conchal resection is the cornerstone of correction of the majority of prominent ear deformities, and it can also be the source of cartilage graft for reconstruction of upper pole deformities. A direct anterior approach to the upper ear, combined with the release of cartilage adhesions and “reshaping” of the cartilage, can be performed alone or in concert with the combined otoplasty techniques to predictably correct a spectrum of upper pole deformities. Understanding the common anatomic deformities, regardless of whether they fall under the classic description of constricted ear, cryptotia, or Stahl’s ear, is more pertinent to the successful correction of the deformity than is the name used to describe the defect.

KEY POINTS

- There is great variability among ears and among ear deformities, and each deformity must be assessed in relation to the normal ear anatomy of the patient and to the differences between the two sides.
- Ear position and projection are significantly affected by abnormalities in the underlying craniofacial skeleton.
- Although the previous literature has emphasized accentuation of the antihelical fold for correction of the prominent ear, my work has clearly demonstrated that chondrocutaneous conchal resection is the cornerstone of otoplasty.
- The group of upper pole ear deformities, including most constricted ears, cryptotia, Stahl’s ear, and some prominent ears (with crimping of the helical rim), can best be corrected with direct exposure of the cartilage defect through an anterior approach and release of cartilage adhesions.
- Whether correcting a constricted ear or an acquired ear deformity, a critical decision must be made: Will the reconstruction match the size of the opposite ear? Or should the emphasis be on normalizing the shape of the reconstructed ear and accepting a size difference?

- Recognizing that we rarely see both of an individual's ears at the same time, differences of 0.5 to 1.0 cm may not be very noticeable, and simpler procedures may often accomplish a better shape without matching vertical height.
- Nonoperative or neonatal splinting for correction of a variety of congenital ear deformities, of which Stahl's ear is the most readily corrected, can be accomplished with simple materials and is most effective if applied within an infant's first 3 months.

Treatment of Major Acquired Ear Deformities

Bruce S. Bauer • Donald Brooks Johnson

The principles gained from treating major congenital ear deformities, especially microtia and the more severe forms of constricted ears, are directly translatable to treating major acquired ear deformities. Although for some surgeons acquired deformities are more a part of their practice than congenital deformities are, it is helpful to have a generalized method of classifying acquired deformities to be able to select the optimal reconstructive technique.¹⁻⁵ I (B.S.B.) have often thought that the simplest way to do this is to separate cases by both etiologic factors and the extent of the soft tissue deficiency. Etiologic factors can be classified as (1) trauma of disease or iatrogenic injury, (2) burn and post-chondritis deformities, and (3) traumatic (non-burn-related) auricular defects. Tissue deficiency can be classified as (1) skin and cartilage deficiency with minimal or “limited” areas of scarring (Fig. 33-1, *A* through *E*) and (2) skin and cartilage deficiency with moderate-to-severe scarring (Fig. 33-1, *F* through *H*).

A critical question that the surgeon must ask patients seeking reconstruction is whether the reconstruction needs to match the opposite normal ear in height, or whether the patient is willing to accept a well-formed reconstruction that may be smaller than the opposite ear? Because we rarely see both ears at the same time, differences of 0.5 to 1.0 cm may not be that noticeable, and simpler procedures may often produce a natural-shaped ear without matching vertical height.

Fig. 33-1 Acquired ear deformities can be classified according to whether there is limited or moderate-to-severe scarring and the extent of missing cartilage. This provides insight into the type of reconstruction that will be required. In **A-C**, three individuals with postchondritis deformity are shown here, each with a limited skin deficiency. **A**, This patient required a contralateral conchal cartilage graft alone. **B**, This individual had a combined ipsilateral and contralateral conchal cartilage graft. **C**, This patient had a costal cartilage framework. **D** and **E**, Two patients with traumatic ear loss are shown in which the adjacent skin is minimally scarred and could be elevated in continuity with the vestige for flap coverage of the replaced costal cartilage framework. **F**, A patient with a failed microtia reconstruction in which the skin is still supple enough to cover a new cartilage framework. **G**, Cartilage loss with moderate-to-severe scarring and loss of the greater part of the ear, with scarring of the surrounding skin resulting from an in utero vascular accident. **H**, This child had a failed reconstruction after eight attempts at reconstructing a lobular type of microtia.

Selection of a simpler approach may be warranted for older patients or when the deformity is the result of tumor resection when the long-term behavior of the resected tumor may be unpredictable. The decision may also be prompted by a desire to have the reconstruction completed with a single procedure rather than with staged procedures that might be required if the full vertical height were reconstructed.

It is possible to decide whether the defect can be reconstructed with adjacent skin flap coverage or whether a fascial flap and skin graft are needed for vascular coverage. It is also possible to determine whether the cartilage defect can be repaired with conchal cartilage (contralateral, ipsilateral, or both) or requires a costal cartilage graft.

An in-depth discussion of each of the many types of acquired deformities is beyond the scope of this chapter; however, a few basic guidelines can be added to the preceding that may aid surgeons in the selection of an ideal approach to the deformity. In general, if the quality of the skin is reasonably good (limited scarring of both the ear remnant and adjacent skin) and the defect is not too large, a more delicate reconstruction can be accomplished with conchal cartilage grafts rather than costal cartilage grafts. However, even if the defect can be bridged with conchal cartilage grafts, a costal cartilage graft may be preferable if fascial flap coverage is required, because conchal cartilage grafts are not sturdy enough to resist the contracting forces of the healing fascial flap. The vascular supply to the ear and postauricular area is excellent, allowing a multitude of flap designs. Although this vascular supply allows considerable ingenuity in choosing a procedure, careful planning can allow the use of the larger, more reliable flaps. Patients should understand that staged procedures are the rule rather than the exception, even though after the initial major reconstruction stage, subsequent procedures may be minor but necessary to obtain an optimal result.

SKIN AND CARTILAGE DEFICIENCY WITH LIMITED SCARRING

Soft tissue deformities with limited scarring, whether they arise from trauma, resection of a tumor, infection, or iatrogenic injury, are characterized by either significant loss of cartilage with minimal injury to the overlying skin (for example, postchondritis deformity) or loss of both skin and cartilage but with limited injury to the skin and surrounding vasculature.⁶ The postchondritis deformity is perhaps the best example of the acquired defect with limited scarring, although small bite injuries and segmental sharp avulsions may likewise fit into this category.

Postchondritis Deformity

The postchondritis deformity is an excellent example, because the skin envelope, even if contracted as a result of scarring from delayed resolution of the infection, is always sufficient to cover the new framework if it is delicately dissected from the remaining amorphous remnant (see Fig. 33-1). The choice of a conchal cartilage (ipsilateral, contralateral, or both) or a costal cartilage framework depends on the size and extent of the cartilage defect (see Fig. 33-1, *A* through *C*). This choice is usually clear before the procedure begins; a template of the normal ear is used as a guide to assess the extent of the defect. Dissection of the overlying skin is best (and most safely) accomplished with an incision just along the edge of the helical rim, with the anterior skin dissected as far as the conchal border (fully exposing the limits of the contracted scapha and anti-helix), and the postauricular skin is dissected to the extent that the mastoid fascia can be accessed for placing supporting sutures⁶ (Fig. 33-2). At this point, the dissection continues to expose the

Fig. 33-2 Reconstruction of a postchondritis deformity. **A** and **B**, Nine months after resolution of an infection that occurred after ear piercing. **C**, Meticulous dissection of the skin flap is required to fully view the deformity and cartilage loss from the helical rim and scapha. **D**, Ipsilateral and contralateral conchal cartilage grafts are positioned where they will be spliced into the remnant. **E**, The skin flap is redraped and fixed to the cartilage with a variable number of fine through-and-through chromic sutures. **F**, Six months after reconstruction. **G** and **H**, Full lateral and closeup views 6 months after reconstruction.

remaining borders of the normal helical crus and helical rim at the borders of the deformed cartilage and normal landmarks. The grafts are then placed, fixing them to the remaining portions of the antihelical body, helical crus at the helical root, and midhelical rim with 5-0 and 6-0 clear nylon. Supporting sutures are placed from the area of the reconstructed scapha and triangular fossa to the temporal and mastoid fascia as the graft with 4-0 clear nylon; these sutures should be placed when the grafts are placed to more easily position the grafts and shape the new upper pole. Although a conchal graft of virtually the whole conchal floor can be harvested as a graft from the contralateral ear, the surgeon should limit the size of ipsilateral conchal graft to ensure that the structural support of the body of the antihelix is not lost. This will still allow a reasonable-sized graft to augment the graft harvested from the contralateral side.

Traumatic Deformities With Limited Skin Loss or Scarring and Segmental Cartilage Loss

The next subgroup of acquired deformities, which still falls within the group of skin and cartilage deficiency with limited scarring, involves traumatic deformities in which upper, middle, or lower pole tissue loss has been limited to the ear without scarring of the postauricular and mastoid skin. Here there is a wide enough area of non-hair-bearing postauricular skin available to cover the replaced missing segment of cartilage (see Fig. 33-2, *D* and *E*). In this group the postauricular and mastoid skin can be elevated in continuity with the border of the defect (as a broad bipediced flap); the cartilage framework is placed beneath this skin and spliced to the remaining auricular remnant, and the ear is elevated in a second stage, with a skin graft applied to the postauricular surface and sulcus (Figs. 33-3 and 33-4).

Incomplete or Failed Reconstruction

Another subgroup of patients that may fit within this broad classification of acquired deformities includes those who have had incomplete or failed reconstruction of microtia or constricted ear deformities.^{7,8} Roughly speaking, if one is seeing more than the rare ear reconstruction patient seeking reoperation, this subset of patients can be further divided into (1) those who have had what can best be described as a rearrangement of the microtic vestige in early childhood but little else until their presentation years later, (2) those who have been through a standard staged reconstruction with a costal cartilage framework who have lost part of the framework because of infection or partial flap compromise with no additional efforts to correct the deformed auricle, and (3) those in whom the initial reconstruction failed and a fascial flap salvage was attempted, which subsequently also failed.⁷⁻⁹ These patients have all of the varied tissue requirements seen in the decision-making process with other acquired deformities.

Fig. 33-3 A, This boy lost the middle third of his left ear at age 14, including the helical rim and a segment of the antihelix, from a dog bite. B and C, The ear 1 year after the injury and just before surgery. D and E, Intraoperatively the defect and the pattern showing the missing segment. F, The result 1 week after coverage of the combined ipsilateral and contralateral conchal grafts with a flap elevated on the border of the defect. G-I, The result 1 year after surgery shows that although the midhelical rim is not prominent on either ear, the symmetry is excellent, particularly as seen in the posterior view.

Fig. 33-4 This 5-year-old girl lost the upper half of her ear when she was bitten by a dog. **A** and **B**, There was no significant scarring on the adjacent postauricular skin, which still included a relatively wide zone of non-hair-bearing skin. This skin was elevated in continuity with the border of the defect as a bipedicle flap to allow splicing of a costal cartilage framework to the existing auricular cartilage. **C** and **D**, Reconstruction was completed with elevation of the ear and reconstruction of the sulcus with a full-thickness skin graft. Results are shown 1 year postoperatively.

It seems intuitive that patients in the first group are good candidates for placing a costal cartilage framework through an approach similar to the typical reconstruction of a lobular or conchal remnant type of microtia with minor variations (Fig. 33-5). However, it may be less obvious that some patients in the second group may also be candidates for a new cartilage framework placed into the same skin envelope. For this group of patients, I (B.S.B.) might previously have used a temporoparietal fascial flap (TPFF) and skin graft for total replacement of the skin envelope; however, following examples demonstrated by Firmin and Marchac,⁵ I (B.S.B.) now recognize that this is not only unnecessary, but also it is often a more extensive procedure than required. If these cases are well selected, the skin coverage is more delicate and has a better color match than a skin-grafted TPFF, and the additional donor scar in the scalp is avoided.

Fig. 33-5 A, This 34-year-old man, who had undergone a single unsatisfactory attempt to reconstruct a conchal remnant type of microtia in childhood, underwent reconstruction through an approach similar to a standard reconstruction. B, After first-stage reconstruction, he still had a relatively limited amount of lobular tissue. C, The ear was elevated and the lobule augmented with a dermal fat graft. D, The result 2 years after further augmentation of the lobule and minor additional soft tissue revision.

What distinguishes skin-grafted TPFF is the thin, supple quality of the skin, which moves freely over the surface of the amorphous framework below. In patients with a skin-grafted TPFF, the skin can be meticulously elevated off the framework through an incision along the helical rim (typically at the junction with the postauricular skin graft), the unacceptable framework removed, the tethering scars released, and the new framework placed (Fig. 33-6). The postauricular graft can typically be raised with some underlying fascia as a flap to add to the overall envelope and in some patients to allow some depth to the postauricular sulcus from the outset. There is a limit to how much conchal excavation can initially be accomplished without compromising the vascularity of the skin envelope. The primary goal of the first reoperation is to place a well-sculpted framework beneath the thin, delicate, flexible skin envelope and to correct any malposition of the earlier reconstruction. After the new framework is in place, subsequent procedures can excavate the concha, construct the tragus, and further define the postauricular sulcus according to the techniques used in a typical successful staged reconstruction.

Fig. 33-6 This 12-year-old girl had undergone multiple unsuccessful reconstructive procedures for a lobular type of microtia. **A**, Despite multiple surgeries and scarring, the skin was still thin and supple and could be used to cover a new cartilage framework. **B** and **C**, The new framework was constructed and placed through an incision along the helical rim, which allowed resection of the old framework and maintained the vascular supply to the flap. **D**, Closeup after elevation of the ear was completed. **E** and **F**, Completed repeat reconstruction and contralateral ear 2 years postoperatively.

Tissue Expansion in the Treatment of Acquired Defects With Limited Scarring

One additional approach that should be discussed briefly before leaving the group of skin and cartilage deformities with limited scarring is the role of tissue expansion in providing additional skin. Some patients present with skin that is deficient but not severely scarred and in whom previous reconstructive efforts have not disrupted the adjacent skin with multiple scars and skin grafts. Several investigators have successfully used tissue expansion in this group of patients^{10,11}; however, the potential risks of expansion (particularly expander exposure) and the need to at least partially excise the expander capsule to ensure adequate skin/cartilage coaptation and vascular ingrowth to the graft may increase the likelihood of flap compromise. In addition, it is rarely possible to expand the skin sufficiently to avoid additional grafting to the postauricular sulcus, which is a benefit frequently mentioned as the primary indication for tissue expansion in these reconstructions. One final caveat is that if one chooses to use tissue expansion for reconstruction of the ear, critical tissues must never be compromised in an effort to salvage an exposed expander. If this

occurs, the expander should be removed, the tissues allowed to settle, and an alternative approach selected to complete the reconstruction.

From a timing standpoint, the tissues and scars need a chance to settle and mature before the reconstruction is initiated. This is particularly important when the skin flap used in the reconstruction will be based along the margin of the defect. In our opinion, the surgeon should wait at least 6 to 12 months from the time of injury or resection, although the amount of time may vary on a case-by-case basis. For patients whose cartilage loss resulted from chondritis, the surgeon should wait until the skin feels soft and mobile. For patients with skin loss and surrounding soft tissue injury, a waiting period of at least 1 year is often prudent. However, if the plan is for reconstruction with a TPFF, the periauricular tissues are uninjured, and the remaining ear is relatively uninjured, an earlier reconstruction can be considered.

SKIN AND CARTILAGE DEFICIENCY WITH MODERATE AND SEVERE SCARRING

Patients who have skin and cartilage deficiency with moderate and severe scarring typically present with either a history of major trauma to the ear and surrounding face and scalp or a history of multiple surgeries with episodes of infection, flap loss, cartilage exposure, and multiple regional flaps for attempted salvage. Often these regional flaps, even if they are performed successfully, may have been delayed long enough, before attempted salvage of the previously failed flap, for the vascularity of the cartilage framework to be compromised; subsequently the outcome is complete cartilage resorption, or significant enough resorption to lose framework integrity. In these patients it is necessary to provide vascular coverage that has not been previously compromised by the previous injury, and coverage with vascularized fascial flaps is the treatment of choice.

Before we discuss specific cases, it is appropriate to specifically look at the role of fascial flaps in ear reconstruction.

Fascial Flaps in Ear Reconstruction

Fascial flaps, although more typically used in treating major acquired deformities of the ear, have had a role in the treatment of microtia cases associated with auricular dystopia and more significant degrees of craniofacial microsomia; they are also used in salvaging complications of microtia reconstruction where scarring obviates the use of the regional skin (Figs. 33-7 through 33-9). A small fascial flap may provide a single-stage reconstruction of a small segmental defect, but it is most often held as a fallback for reconstruction of more complex defects.

Temporoparietal Fascial Flap

The TPFF is the most commonly used of the fascial flaps in complex ear reconstruction, although the postauricular fascial flap and deep temporal fascial flap may occasionally be used. The TPFF may also be used as a free flap when previous trauma or iatrogenic injury has compromised the ipsilateral fascial vascular supply. The flap is supplied by both the superficial temporal artery (STA) and postauricular artery (PAA), and although the flap is typically elevated on the STA alone, both vessels should be included to minimize the risk of partial flap necrosis whenever possible. Although the TPFF has also been used as a random flap by Brent and Byrd,¹² this type of flap is generally not recommended.

Fig. 33-8 A, Extensive loss of the greater part of the ear, with extensive scarring surrounding the ear and extending onto the cheek, appeared to be the result of this young girl's intrauterine vascular accident, which resulted in compromise to the ear blood supply and loss of both ear skin and cartilage. B, Reconstruction was carried out with a costal cartilage framework covered with a TPF and a split-thickness skin graft. She is shown 1 year after a two-stage reconstruction. C, One year postoperatively.

Fig. 33-9 A, This 7-year-old girl had undergone seven previous attempts at reconstruction of a lobular type of microtia, which resulted in a small amorphous ear. B, A new framework was placed and covered with a TPF and split-thickness skin graft, retaining enough of the original tissue to create the tragal prominence and lobule. C, At 3 months postoperatively (after the first stage of repeat reconstruction), the fascial flap was thinning and the details of the ear were more evident. D, Result of the one-stage repeat reconstruction, seen 6 years later. E and F, Symmetry with the contralateral normal ear can be seen.

The postauricular fascial flap supplied by the PAA and occipital arteries is a continuation of the TPFF (superficial temporal fascia). The deep temporal fascial flap is supplied by the middle temporal artery, which arises from the STA.^{8,9} It may also include a branch of the PAA. Both of these flaps may play a role in secondary or reoperative ear surgery, particularly as salvage after failure of the TPFF. Although the former is quite effective for coverage of small areas of skin or flap loss in the middle and lower third of the ear (and on occasion is even preferred over the TPFF), these other flaps are used relatively rarely.

If a previous failure to replant and attempt salvage has not compromised the STA, or at least has left a clearly defined length of the PAA and occipital arteries, and there is still donor costal cartilage available, the surgeon can consider discarding most or all of the previous ear vestige. An effort should be made to keep the usable parts of any ear remnant as would be done when reconstructing a conchal remnant microtia. At the very least the surgeon should retain enough tissue to reconstruct the lobule^{3,13,14} (see Fig. 33-9).

Careful assessment of the surrounding scars (including careful inspection for any hidden scalp scars) and mapping potential vascular pedicles with a Doppler probe are key factors in performing these complex reconstructions. I (B.S.B.) have seen more than a few patients in whom there was a failed reconstruction or patients who had undergone prior procedures in the early postinjury period that left scars within the scalp at surgical sites that defied logic and that further complicated reconstruction. The TPFF is the most commonly used fascial flap for complex ear reconstruction, and in some cases the surgeon may need to be innovative in its design while still respecting the vascular anatomy^{3,13,14} (Fig. 33-10). Alternative choices include the postauricular fascial flap and free tissue transfer of the TPFF from the contralateral side⁷⁻⁹ (Fig. 33-11).

Fig. 33-10 A and B, At age 10 years this girl sustained extensive burns in a terrorist attack, resulting in the loss of most of her scalp and the greater part of her left ear.

Continued

Fig. 33-10, cont'd C-K, To avoid potential loss of the limited remaining normal scalp, the incisions were oriented to preserve the scalp and allow adequate skin flap elevation off the remaining cartilage vestige and thin coverage of the framework as it was spliced into place. The TPF was oriented on the anterior branch of the STA and covered the upper pole of the reconstruction. The greater part of the reconstructed framework was covered by the thin and pliable postauricular skin that was elevated in continuity with the border of the defect. The fascial flap was then covered with a split-thickness skin graft.

Fig. 33-10, cont'd **L**, The result 4½ years after first-stage reconstruction. **M**, The result 2 years after second-stage reconstruction, which involved scar revision and the insertion of dermal fat grafts into the lobule. At the second-stage reconstruction, she also underwent brow reconstruction with micro hair grafts. Her insufficient normal hair-bearing scalp prevents scalp reconstruction with either tissue expansion or micrografting.

Fig. 33-11 **A-E**, This 18-year-old girl sustained extensive soft tissue injuries, including the loss of the soft tissue of her lateral cheek, the greater part of her left ear, and the underlying superficial temporal fascia. She underwent a series of reconstructive surgeries, including free tissue transfer, which provided a lobular segment of tissue usable for earlobe reconstruction but was positioned anterior and inferior to the planned reconstruction.

Continued

Fig. 33-11, cont'd M and N, Seven months after first-stage reconstruction, the second stage involved lobule and tragus construction from anteriorly displaced remnants and banked “tragal” cartilage grafts. O and P, Two weeks after second-stage reconstruction. Q, Four years after first-stage reconstruction and before the final stage including facial scar revision. R and S, Three months after final-stage ear reconstruction.

Grafted Fascial Flap

Staging the reconstruction is similar to that described for complex microtia cases in which a fascial flap is required for vascular coverage. Templates are made for the framework and placement of the ear. Cartilage is harvested and the framework is constructed. The framework is placed and covered with the fascial flap, and the flap is covered with a split-thickness skin graft, with the scalp the preferable donor site for the graft. Vacuum drains are placed beneath the framework and flap and beneath the donor scalp flaps. The postoperative treatment is similar to that used for standard reconstruction, but the time between the first (new reconstructive stage) and subsequent stages may be longer than with skin flap coverage. Grafted fascial flaps are quite variable in the time course of thinning to show the underlying cartilage details. Regardless of the progress, I (B.S.B.) often wait at least 6 months between the first and subsequent stages. Patients must be aware that in some cases, the thinning may take as long as 1 year before the framework details are well defined. One can expect continued thinning along with improvement of skin color and flexibility of this flap over at least 2 to 3 years, if not longer. If the surgeon has properly prepared these individuals for their repeat reconstruction, they generally are accepting of the slow healing process and are patient enough to look toward the final result, even if it takes months or years (see Figs. 33-9 through 33-11).

PROSTHETIC RECONSTRUCTION

Not surprisingly, the success of reconstruction of acquired deformities, regardless of cause, depends significantly on careful case selection. Most often, except for individuals with previous limited surgery and limited scarring, the surgeon should consider and discuss the possibility of prosthetic reconstruction. At the very least, any patient who has a history of multiple previous ear reconstructions and is dissatisfied with the size, shape, position, and lack of fine detail in the outcome should be evaluated for prosthetic reconstruction.^{15,16} This includes patients who have had previous reoperative surgery with cartilage harvested from both sides of the chest and patients who have lost the ear as a result of tumor resection who require long-term monitoring for possible tumor recurrence. Patients should meet with both the surgeon involved in the osteointegration of the abutment for the prosthetic ear (if it is not you) and the anaplastologist who will be creating the prosthesis. They should understand not only the obvious benefits of an excellent match in size, shape, and color with the current prosthesis, but also the long-term need to replace the prosthesis, maintenance of the abutment, and the costs of prosthetic replacement.

In my practice, even in patients in whom I (B.S.B.) am confident of the success of an autologous reconstruction, I (B.S.B.) evaluate the patient for a prosthetic reconstruction and discuss this option, because this ensures that he or she is making an informed decision when proceeding with a new set of staged procedures. This routine also provides a means of informing the patient of an additional “final option” if reconstruction is unsuccessful (Fig. 33-12).

Fig. 33-12 A, This young boy had an unusual sarcoma involving his right ear. He had had multiple recurrences and ultimately the ear was removed. His mother was a nurse and did not want an autologous reconstruction, because she wanted to watch for recurrences. B, The prosthesis fabricated for the reconstruction. C, The osteointegrated prosthesis in place, which he has worn for 15 years. (Courtesy of Gordon H. Wilkes, MD.)

CONCLUSION

Successful staged reconstruction of the ear for major acquired ear deformities requires meticulous attention to all aspects of the available auricular and donor tissue and the soft tissue environment surrounding the planned reconstruction. Because there is considerable variation in auricular remnants, meticulous planning is perhaps the most important factor in reducing complications.

The challenges faced during successful reconstruction of “virgin microtia,” or the first attempt at reconstruction of an acquired ear deformity, are significantly magnified when these procedures have already failed and the patient presents for reoperation. Secondary surgery to correct a previously unsatisfactory result must take into account that the recipient bed is now scarred and the

donor tissues are more limited. Successful reoperation requires familiarity with all available reconstructive options and the expertise of the operating surgeon. The surgeon must ensure that the patient understands the complexity of the surgery and that the reconstruction will probably be staged. The surgeon must also be reasonably certain that the patient's expectations and the surgeon's capabilities are in sync. Finally, the alternatives of accepting the current result at one end of the spectrum and prosthetic reconstruction at the other end must always be considered and discussed. With these issues in mind, the surgeon, with consummate skill and a little good luck on occasion, will see that the patient does not require additional reoperation.

KEY POINTS

- The principles of treating congenital ear deformities are directly translatable to the treatment of acquired ear deformities.
- Classifying acquired ear deformities into two groups—those with skin and cartilage deficiency with limited scarring and those with skin and cartilage deficiency with moderate-to-severe scarring—allows a surgeon to develop a readily applied treatment algorithm for any and all acquired deformities.
- Careful appraisal of the defect, donor tissue, and the surrounding soft tissue is imperative to selecting the optimal reconstructive modality.
- When correcting an acquired ear deformity, a critical decision must be made: to reconstruct to match the size of the opposite ear or to normalize the shape of the reconstructed ear and accept a size difference.
- Because both ears are rarely seen at the same time, differences of 0.5 to 1.0 cm may not be very noticeable, and simpler procedures may often produce a better shape without matching vertical height.
- Fascial flaps are important sources of tissue that can be used in salvage or secondary reconstruction procedures, or when local skin flaps cannot achieve adequate coverage of the auricular framework.
- All treatment options, including prosthetic reconstruction or potentially accepting the ear in its defected state, should be considered and thoroughly discussed before initiating treatment.

Congenital and Acquired Deformities of the Eyelids

Milap Mehta • Bruce S. Bauer

eyelids exist to protect the eye, the most complex of human sensory organs. Their multilamellar structure provides glands that lubricate and irrigate the cornea, on whose transparency we rely for our detailed view of the world around us. The fibrocartilaginous tarsal plates provide delicate structural support, and the opposing orbicularis oculi and levator palpebrae muscle systems allow rapid blink and reflex closure to protect against particles or insects headed toward the cornea.

The development of visual acuity in newborns depends on the reception of visual images on an infant's retina. If growths or abnormalities in or around the eyelids prevent reception of these images, vision will not develop in the eye, a condition known as *amblyopia ex anopsia*. For this reason, a condition such as cryptophthalmia (fusion of the eyelids over an otherwise normal eye) or a hemangioma of the eyelid that completely blocks vision should be treated as a medical emergency. Similarly, an infant with a coloboma of the upper eyelid, or extreme proptosis, should be treated immediately to prevent corneal scarring or perforation and loss of the eye. After the period of visual development, the protection of the globe becomes the paramount function of the eyelids. Trauma with laceration or avulsions of the eyelid, often associated with facial fractures, will require careful and complete repair to preserve the eye.

DEVELOPMENT

The clinical significance of understanding these developmental processes cannot be underestimated, because it may help to understand the mechanisms of the development of many congenital anomalies. The development of the eye begins with a thickening of the diencephalic neural folds at 22 days' gestation. The eyelids form as ectodermal folds between week 6 and week 8 of development. As the lid folds advance and fuse, uniting by week 12 to week 14, they form an internal

pocket that covers the eye and differentiates on the deep surface to form the conjunctiva and its adnexa, including, at 6 to 8 weeks of age, the lacrimal gland.^{1,2}

The lacrimal drainage system develops as an ectodermal cord between the lateral nasal process and the maxillary process. The epithelial cord canalizes from month 3 to month 6 of gestation. The punctum remains closed until the month 7, and the nasolacrimal duct may not canalize until just before birth. Canalization of the nasolacrimal duct may be incomplete in up to 30% of newborns, but only a small number of these become symptomatic, because the duct usually opens spontaneously.

Subsequent development of the tarsal plates, lash follicles, and meibomian, Zeis, and Moll glands occurs until about weeks 22 through 24 of gestation. At that time, or within weeks after, the fused lids separate into the upper and lower eyelid.

Alterations in these developmental processes can lead to a wide variation of anomalies,^{3,4} as shown in Table 34-1. For example, colobomas and clefts may occur from inadequate fusion of the

Table 34-1 Some Syndromes With Ocular Abnormalities

Syndrome	Comments (chromosome map locations)
Aicardi syndrome	Lacunar retinopathy Probably X-linked dominant; lethal in male hemizygotes (Xp22)
Alagille syndrome	Posterior embryotoxon, pigmentary retinopathy Autosomal dominant; <i>JAG1</i> mutations (20p12)
Anophthalmia-syndactyly syndrome	Autosomal recessive
Apert syndrome	Ocular proptosis
Baraitser-Winter syndrome	Iris coloboma, ptosis, hypertelorism Autosomal recessive
Biemond syndrome II	Iris coloboma Autosomal dominant
Blepharophimosis-ptosis-epicanthus inversus	Autosomal dominant; <i>FOXL2</i> mutations (3q23)
CHARGE association and Hall-Hittner syndrome	Colobomas, sporadic, some familial cases
CHIME syndrome	Colobomas Autosomal recessive
Chondrodysplasia punctata	Cataracts Genetically heterogeneous Conradi-Hünermann type, X-linked dominant; <i>EPB</i> mutations (Xp11.22-p11.23) Rhizomelic type, autosomal recessive; <i>PEX7</i> mutations (6q22-q24)
Cohen syndrome	Retinal mottling, constricted visual fields, other ocular abnormalities Autosomal recessive; <i>COH1</i> mutations (8q22-q23)
Crouzon syndrome	Ocular proptosis
Cryptophthalmos syndrome	Autosomal recessive; <i>FRAS1</i> mutations (4q21)
Delleman syndrome	Orbital cysts, microphthalmia, colobomas All cases sporadic, to date

CHARGE, Coloboma, heart defect, atresia choanae, retarded growth and development, genital abnormality, and ear abnormality. *CHIME*, coloboma, heart defects, ichthyosiform dermatosis, mental retardation, and ear anomalies with hearing loss.

Syndrome	Comments (chromosome map locations)
Ehlers-Danlos syndrome, type VI	Keratoglobus, other ocular abnormalities Autosomal recessive
Fabry syndrome	Aneurysmal dilation and tortuosity of conjunctival and retinal vessels, characteristic corneal and lenticular alternations X-linked recessive; <i>GLA</i> mutations (Xq22)
Familial dysautonomia	Decreased tears, absent corneal reflex, other ocular abnormalities Autosomal recessive; <i>IKBKAP</i> mutations (9q31)
Fetal alcohol syndrome	Narrow palpebral fissures, small eye globes
Focal dermal hypoplasia	Colobomas X-linked dominant, lethal in male hemizygotes
Goldenhar syndrome	Epibulbar dermoids, other ocular abnormalities Most cases are sporadic, some have autosomal dominant inheritance
Hallermann-Streiff syndrome	Congenital cataracts, microphthalmia, other ocular abnormalities All cases are sporadic
Holoprosencephaly	Ocular hypotelorism, single eye globe in cyclopia, other ocular abnormalities Causatively heterogeneous
Homocystinuria	Ectopia lentis (inferior dislocation), other ocular abnormalities Autosomal recessive; <i>CBS</i> mutations (21q22.3)
Kaufman syndrome	Upslanting palpebral fissures, sparse eyebrows, blepharophimosis, myopia, microcornea, pale optic disks
Lenz microphthalmia syndrome	Microphthalmia, anophthalmia X-linked (Xq27-q28)
Marden-Walker syndrome	Blepharophimosis, other ocular abnormalities Autosomal recessive
Marfan syndrome	Ectopia lentis (superior dislocation), other ocular abnormalities Autosomal dominant; <i>FBNI</i> mutations (15q21.1)
Marshall syndrome	Myopia, cataracts Dominant inheritance, autosomal dominant versus X-linked dominant Basic defect is controversial; <i>COL1A1</i> (1p21) may be a candidate gene, but this has been debated.
Megalocornea and mental retardation	Four types: Neuhäuser syndrome, Frank-ter Haar syndrome, Verloes syndrome, and Frydman syndrome
Michels syndrome	Blepharophimosis, ptosis, epicanthus Autosomal recessive
Moebius syndrome	Seventh nerve palsy If syndrome is defined as involvement of both sixth and seventh nerve palsies, almost all cases are sporadic.
Mucopolysaccharidoses	Corneal opacities in types I-H (Hurler), I-H/S (Hurler-Scheie), I-S (Scheie), IV-A (Morquio A), IV-B (Morquio B), VI-A (Maroteaux-Lamy A), and VI-B (Maroteaux-Lamy B)
Nance-Horan syndrome	Congenital posterior cataracts X-linked (Xp22.13-p22.31)
Neurofibromatosis	Type I Lisch nodules, occasionally pulsating exophthalmos caused by bony defect of posterosuperior orbital wall, uncommonly optic glioma Caused by <i>NF1</i> mutations (17q11.2) Type II Senile lens opacities or subcapsular cataracts Caused by <i>NF2</i> mutations (22q12.2) Types I and II: autosomal dominant

Continued

Table 34-1 Some Syndromes With Ocular Abnormalities—cont'd

Syndrome	Comments (chromosome map locations)
Osteogenesis imperfecta	Blue sclera in types II and III <i>COL1A1</i> mutations (17q21.31-q22) or <i>COL1A2</i> mutations (7q22.1) in both types II and III
Peters-plus syndrome	Consists of central corneal opacity, thinning of the posterior cornea, and iridocorneal adhesions Also found: anterior chamber defects and other ocular anomalies Autosomal recessive; a mutation in <i>PAX6</i> (11p13) in one case and a mutation in <i>RIEGL</i> in another
Pfeiffer syndrome	Ocular proptosis
Rieger syndrome	Abnormal development of the anterior chamber of the eye Autosomal dominant; <i>RIEGL</i> mutations (14q25-q26)
Rubella syndrome	Cataracts
Stickler syndrome	Type I High myopia with retinal detachment, cataracts Autosomal dominant; <i>COL2A1</i> mutations (12q13.11-q13.2) Type II Severe, early onset and retinal degeneration Autosomal dominant; <i>COL1A1</i> mutations (1p21)
Trisomy 21 syndrome	Upslanting palpebral fissures, epicanthic folds, Brushfield spots, fine lens opacities, convergent strabismus, nystagmus, keratoconus, cataract, rare retinoblastoma
Trisomy 13 syndrome	Microphthalmia, iris coloboma, retinal dysplasia
Trisomy 18 syndrome	Various abnormalities of the eye globe, adnexa, and neuroophthalmologic system
Tuberous sclerosis	Retinal hamartomas Autosomal dominant; mutations in either <i>TSC1</i> (9q34) or <i>TSC2</i> (16p13.3)
Velocardiofacial syndrome	Narrow palpebral fissures, blue suborbital coloring, tortuous retinal vessels, posterior embryotoxon, small optic disks, cataracts, colobomas Autosomal dominant (22q11.2)
Waardenburg syndrome	Type I Heterochromia irides, dystopia canthorum Autosomal dominant; <i>PAX3</i> mutations (2q35) Types IIA and IIB Heterochromia irides without dystopia canthorum Type IIA: autosomal dominant; <i>MITF</i> mutations (3p12.3-p14.1) Type IIB: autosomal dominant (1p13.3-p21) Type III Klein-Waardenburg syndrome, heterochromia irides, dystopia canthorum, limb defects Autosomal dominant; <i>PAX3</i> mutations (2q35) Type IV Waardenburg-Shah syndrome, heterochromia irides without dystopia canthorum, associated Hirschsprung disease Causatively heterogeneous Mutations in <i>EDHRB</i> (13q22) or in <i>EDN3</i> (20q13.2-q13.3); both are autosomal recessive; or in <i>SOX10</i> (22q13), autosomal dominant
Wagner syndrome	Hyaloideretinal degeneration, chorioretinal atrophy, cataract, peripheral retinal detachment, glaucoma Autosomal dominant (5q13-q14)
WAGR	Wilms tumor, aniridia, gonadoblastoma, mental retardation del(11)(p13)
Walker-Warburg syndrome	Microphthalmia and many other ocular abnormalities Autosomal recessive; <i>POMT1</i> mutations (9q34.1) and <i>FCMD</i> mutations (9q31)

Syndrome	Comments (chromosome map locations)
Weill-Marchesani syndrome	Spherophakia Causatively heterogeneous Autosomal dominant form with <i>FBNI</i> mutations (15q21.1) and autosomal recessive form (19p13.2-p13.3)
Werner syndrome	Senile cataracts Autosomal recessive; <i>RECQL2</i> (8p11.2-p12)
Williams syndrome	Stellate iris, strabismus Contiguous gene syndrome involving <i>ELN</i> (7q11.2)
Wilson disease	Kayser-Fleischer rings Autosomal recessive; <i>ATP7B</i> mutations (13q14.3-q21.1)

Table 34-2 Duke-Elder's Pathology of the Eyelids

Stage of Development	Pathology	Conditions
First trimester (early)	Failure of formation	Cryptophthalmos Microphthalmos Colobomas
Second trimester (5 to 6 months)	Failure of formation	Ankyloblepharon Congenital ectropion Entropion
Third trimester (late)	Failure of differentiation	In the tarsus, palpebral musculature, and lid skin

processes of the embryonic lid folds. Cryptophthalmos is caused by failure of the lid folds to develop, whereas anophthalmos or microphthalmos may result from abnormalities in development of the optic vesicle. Melanocytes migrate in the lids before separation, explaining the occurrence of a so-called dividing or kissing nevus. Other lid abnormalities such as epiblepharon, entropion, and ectropion are the result of minor abnormalities in development.

Duke-Elder³ classified the pathology of the eyelids on the basis of chronologic fetal development (Table 34-2).

Tessier^{5,6} classified facial clefts numerically based on their anatomic locations. The clefts are defects resulting from inadequate fusion of soft tissue and bone. The eye, including the eyelids, the orbital cavity, and the brain, reach adult dimensions by 7 to 8 years of age. With the aging process, from middle age into old age, looseness of the skin and ligamentous attachments and dehiscence of the levator aponeurosis are responsible for conditions not generally seen in children. Reconstructive procedures in children, however, use many of the same techniques used in adults.

NORMAL AND ABNORMAL ANATOMY

Eyelids are a highly complex structure composed of an anterior and posterior lamella separated by the orbital septum (Fig. 34-1). Skin and orbicularis oculi form the anterior lamella. The upper lid posterior lamella consists of the conjunctiva, Müller's muscle, levator aponeurosis, and tarsus.

Fig. 34-1 **A**, A lateral view of the eyelid. Upper and lower tarsal plates are evident, with the orbital septum running from the upper portion of the tarsus to the orbital rim and the levator muscle attaching to the levator aponeurosis, which attaches to the tarsus. **B**, A frontal view of the eyelid. The lateral canthal tendon is slightly higher than the medial canthal tendon. The upper and lower puncta pass through canaliculi to the lacrimal sac. The lacrimal conduit passes to its exit point beneath the inferior turbinate. **C**, A deeper view of the orbital structures.

The lower lid posterior lamella is made of the conjunctiva and capsulopalpebral fascia. The upper tarsus is approximately 10 mm high, whereas the lower tarsus is up to 4.5 mm high.⁷⁻⁹

The orbicularis oculi is innervated by the seventh cranial nerve. The eyelid closes on contraction of this muscle. The orbicularis oculi is divided into three muscles: pretarsal, preseptal, and orbital.^{7,8} The levator muscle, innervated by the third cranial nerve, and Müller's muscle, innervated by sympathetics, together raise the upper eyelid. The levator muscle originates at the lesser wing of the sphenoid. It forms the aponeurosis and inserts onto the tarsus.⁸ The lateral attachment ends at the lateral retinaculum, and the medial attachment ends at the posterior lacrimal crest. The distance the upper eyelid moves from downward to upward gaze is a measure of levator function. Müller's muscle, a smooth muscle, originates at the posterior part of the levator and inserts onto the superior part of the tarsus. It is found in the upper lid posterior lamella and is attached to the levator and tarsus. Injury to Müller's muscle results in a 2 to 3 mm ptosis.⁷

The orbital septum prevents the spread of infection and bleeding from the eyelid to the posterior orbital structures. The septum starts at the orbital rim and inserts above the tarsal border into the upper lid and below the tarsal border into the lower lid.^{7,8}

The lateral canthus (or retinaculum) consists of the inferior suspensory ligament (Lockwood's ligament), the levator aponeurotic lateral extension, the pretarsal and preseptal muscle extension, and the lateral rectus check ligament. The lateral canthus inserts in the Whitnall tubercle, located at the lateral orbital wall or the zygoma. This is clinically significant, because inferiorly displaced zygoma fractures cause the palpebral fissure to have a downward slant by pulling down on the lateral canthus. The medial canthus has three insertion points: the anterior lacrimal crest, the nasal bone—close to the nasofrontal suture—and the posterior lacrimal crest. The lacrimal sac is found between the anterior and posterior insertions of the medial canthus.⁷⁻¹⁰

All of the extraocular muscles except the inferior oblique originate near the orbital apex at the annulus of Zinn. The origin of the inferior oblique is the anterior orbit. This muscle separates the lower lid medial and central fat compartments.⁷

The supratarsal fold is the fold of skin above the dermal attachments of the levator aponeurosis and is usually absent in people of Asian descent. This fold is usually 1 cm above the eyelid margin and, if in a high position, the cause may be a levator defect.⁷

The orbit fascial framework comprises extraocular muscle-investing fascia, bulbar fascia, Tenon's fascia, the intermuscular septa, and the check ligaments, which are formed by the medial and lateral rectus muscles. Lockwood's ligament is formed by the intermuscular septum, which is between the inferior rectus and inferior oblique.^{7,10}

Eyelids are important for tear production, because they directly influence the pumping mechanism. Pretarsal muscle causes negative pressure inside the lacrimal sac by pulling on the lacrimal diaphragm. With relaxation, tears enter the nasolacrimal duct. Vertical movement of the eyelids lubricates the eyes and forms a visual axis. Eyelashes filter ultraviolet light and foreign bodies. The medial eyelids contain the canalicular drains. There are several glands along the eyelid margin. Approximately 30 meibomian glands are located within the tarsus of each lid. Apocrine glands of Moll and the pilosebaceous glands of Zeis are found in the distal eyelid margin, anterior to the meibomian glands, which form the lipid part of tears.^{4,8,9}

PREOPERATIVE ASSESSMENT

The highest priority in the management of eyelid deformities is to prevent interference with the normal development of vision.⁴ Therefore the globe must be protected from trauma and desiccation. Before the maturation of vision, prolonged, significant occlusion of the visual axis may result in a deprivation amblyopia. Although many of the conditions that present in this region require evaluation and treatment by multiple specialists, an ophthalmologic consultation should be sought early in the diagnosis and treatment. Full fundoscopic and slit lamp examinations performed with the patient under general anesthesia may be essential.

Few conditions require urgent treatment; these include rapidly enlarging lid and orbital hemangiomas (with risk of either occlusion of the visual axis or late anisometropic amblyopia from deformation of the globe), exposure of the cornea caused by coloboma, and marked exorbitism⁴ (Figs. 34-2 and 34-3). Beyond these conditions that present in the neonatal period, these conditions can occur in infants and even in older children who present to pediatric plastic surgeons. It is critical to understand the initial deformity, the extent of previous treatment, and the duration of the eyelid problem for which the parents are seeking evaluation and/or treatment.

An examination of the eyelids should be systematic, beginning with the upper eyelid. A normal resting lid position is 2 mm below the superior corneoscleral junction. If the lid droops lower, it is considered ptotic. The eyelid should also be evaluated for incomplete closure and retraction. Lesions of the eyelid are assessed for size, location, discoloration, and any associated ulceration

Fig. 34-2 A, This newborn infant was born with a severe form of Treacher Collins–Franceschetti syndrome and was tracheotomized at birth. B and C, The first priority after securing her airway was to correct the left cryptophthalmia, taking the remnant of the lower eyelid and turning it upward to join with the remnant of the upper eyelid. Although the underlying eye is not entirely normal, because it has a coloboma of the iris, the patient has useful vision. D, The patient is shown after a partial correction of her lateral facial clefts, opening of her nasal airways, and correction of an encephalocele. The mandible has been distracted, and a distraction of the LeFort II segment will be performed. (Courtesy of S. Anthony Wolfe, MD.)

Fig. 34-3 A, This newborn infant had Pfeiffer's syndrome and extreme proptosis resulting from almost nonexistent orbital cavities. B and C, He is shown after two intracranial monobloc frontofacial distractions; the orbital cavities have been developed adequately to allow opening of the tarsorrhaphies. (Courtesy of S. Anthony Wolfe, MD.)

or lash loss. The lower eyelid is inspected for malpositions such as outward turning, referred to as *ectropion*, or inward turning, known as *entropion*. The eyelashes are inspected for misdirection that can irritate the cornea. Some of these deformities and conditions are best treated by a plastic surgeon, whereas others should be treated by a pediatric ophthalmologist. Often, optimal care requires the experience of both specialists.

Pathology of the eyelids can involve soft tissue only or bone and soft tissue. It can arise as an excess, a deficiency, or an aberration from any of the anatomic sites and their components. Although this discussion of defects as separate entities is somewhat arbitrary, it provides a useful framework for discussing many of the congenital presentations. A discussion of the acquired deformities follows. Many of the techniques used in the correction of congenital deformities arose from the reconstruction of acquired defects in adults. Conversely, as combined soft tissue and skeletal reconstruction expanded with Tessier's work and the field of craniofacial reconstruction, the techniques that were designed to correct complex congenital defects were adopted for treating adult eyelid deformities.

Timing of Treatment

The timing of surgical repair of the eyelids depends on the nature of the deformities. Many children with craniofacial syndromes need multiple surgeries arranged in a coordinated fashion. If the globe is becoming desiccated or vision is at risk, eyelid surgery should be performed soon. However, if cosmesis is the main concern, eyelid surgery may be delayed.³

Several important factors require consideration for successful pediatric eyelid surgery. The risk of amblyopia is greater in younger children. Disrupting the binocular vision for even a few days can result in amblyopia. Misalignment of the eyes, occlusive dressings or ointments, and large eyelid masses or flaps can result in vision deprivation and induce amblyopia. The child should be examined by an ophthalmologist if any of these may possibly occur.³

In pediatric patients, the use of absorbable sutures eliminates the need for suture removal. Elbow splints may be necessary to prevent the need for dressing removal and disruption of wounds by the child. To prevent amblyopia, surgeons should not use occlusive dressings or ointments for a prolonged period.⁴

Congenital Deformities of the Eyelid

DEFORMITIES OF THE UPPER EYELID—SOFT TISSUE

Coloboma

A coloboma of the eyelid is defined simply as an eyelid defect. Most occur in the upper eyelid, usually in the medial aspect. They vary in extent from minimal notches to almost complete lack of development of the full-thickness upper eyelid. Colobomas are typically triangular with the base at the lid margin, but defects can be quadrilateral, oval, or irregularly shaped (see Fig. 34-2). Usually, the absence involves all of the lid structures, including skin, orbicularis, tarsus, conjunctiva, lashes, and glands. Partial defects are rare.⁴

The most common position for an eyelid coloboma is at the junction of the medial and middle third of the upper eyelid. Lateral colobomas affecting the lower eyelid are most commonly seen in combination with other soft tissue and skeletal anomalies, as in Treacher Collins syndrome and Goldenhar syndrome^{11,12} (see Table 34-1).

The timing of coloboma repair depends on the degree of corneal exposure caused by the defect. The repair of small or intermediate defects without associated irritation or drying of the cornea may be delayed until the child is 3 to 5 years of age. However, many surgeons prefer to

carry out the reconstruction as soon as the child is a safe anesthetic risk to restore function early and to prevent the possible later stigmata of the deformity as the child approaches school age.

The method of repair depends on the size and location of the defect. Most colobomas are small defects involving less than 30% of the eyelid and can usually be repaired by primary closure. Larger defects, involving 30% to 50% of the lid, will require a lateral canthotomy to obtain adequate relaxation of the lid margin and prevent ptosis caused by a tethering effect on the taut lid. Defects involving more than 50% of the lid margin may necessitate a major lid reconstruction such as a rotation flap created from the lower eyelid.

Defects of the lower eyelid, as seen in the varied oroocular clefts and Treacher Collins syndrome, require a reconstruction of the skeletal and soft tissue components.^{13,14} These will be reviewed in greater detail in the discussion of Tessier clefts, later in this chapter and in Chapters 26 and 30. In the lower lid, three layers need to be reconstructed: the skin, the supporting layer, and the conjunctiva. Skin grafts or a flap may be required to replace the skin. A Mustardé cheek advancement flap is one of several flaps appropriate for filling a large defect of lower lid tissue. The surgeon may need to provide added support (cartilage) or lining (conjunctiva) if more than 30% of the lower lid tissue is missing.^{9,13} Buccal and nasal mucosal grafts can be used to replace conjunctiva, or a septal chondromucosal graft may be used to replace both the intermediate supporting layer and lining as a single graft.

Ptosis

Congenital ptosis is defined as eyelid drooping that presents in the perinatal period. However, recognition of the defect may be delayed because of lid edema in the neonatal period or failure to recognize differences in the two lids when the condition is unilateral.

Congenital ptosis can be sporadic or familial. It is usually unilateral. It may be seen alone or in combination with other extraocular muscle weakness, particularly of the superior rectus muscle.^{4,15,16} Other variants of congenital ptosis include symmetrical ptosis, which is common, and Marcus Gunn ptosis, which is rare. Blepharophimosis is another variant. It involves a decreased palpebral aperture with ptosis, epicanthus, and telecanthus. This can occur as part of a complex of anomalies in blepharophimosis syndrome (Figs. 34-4 through 34-6).

Congenital ptosis seems to arise as a result of a deficiency of striated muscle in the levator palpebrae muscle.¹⁵ This ranges from very mild to near total absence of the muscle (Table 34-3). The severity of muscle deficiency seems to be proportional to the severity of the ptosis and the lack of levator function.

A clinical assessment of ptosis includes the birth history and the family history. The progression of the ptosis, the visual status, and the status of extraocular muscle function should be recorded. Regardless of which surgical discipline will be involved in treating the ptosis, a full examination should ideally be performed by a pediatric ophthalmologist, and visual acuity and extraocular muscle function should be recorded.

Table 34-3 Grades of Ptosis and Levator Function

Ptosis (mm)	Levator Function (mm)
Mild: 2-3	Good: 10-15
Moderate: 3-5	Fair: 6-9
Severe: >5	Poor: <5

Fig. 34-4 **A**, This patient had blepharophimosis with the characteristic telecanthus, epicanthus inversus, ptosis, lack of fixation of the lateral canthus, and short transverse palpebral fissures. **B**, The patient is shown after transnasal medial canthopexies with Z-plasties in the medial canthal area and a lateral canthopexy and a small calvarial bone graft to the nose. The canthopexy wires were tightened over the nasal bone graft through a short incision. (Courtesy of S. Anthony Wolfe, MD.)

Fig. 34-5 The Fasanella-Servat procedure (tarsconjunctival mullerectomy) is indicated for patients with good levator excursion and mild ptosis. **A**, Mild upper lid ptosis of 1 to 2 mm. **B**, Running suture (full-thickness) is placed behind the clamps from lateral to medial. **C**, A cross-section of the suture placement. **D**, Excess clamped tissue is trimmed. **E**, Closure: Suture is tied on the skin surface and covered with a Steri-Strip bandage.

Fig. 34-6 **A**, A frontalis sling tethers the upper eyelid to the frontalis muscle above by way of alloplastic or autogenous material tunneled beneath the orbicularis oculi muscle. A protective contact lens is placed on the eye. **B**, Suspension material is placed subcutaneously to create a static sling. Insert shows a suture loop through the knot tied in the suspension material, allowing later access to the knot and earlier postoperative adjustment of the correction.

The presence of a chin-up head posture should be noted during the examination of a child with congenital ptosis. Such posture can result in neck problems and visual axis occlusion. This may affect ocular motility, levator function, and the location of the eyelid crease. Levator function can be measured by the amplitude of the excursion from downward gaze to maximal upward gaze. If levator function is adequate, the chances for a good repair and adequate lid level after surgery are improved.

The examiner should stabilize the brow with his or her finger to measure the true excursion of the lid. The usual guidelines for measurement and treatment depend on the adequacy of levator function. Finally, the child is tested preoperatively for evidence of Bell's phenomenon. This is a test of the ability of the globe to rotate upward during sleep, an important reflex when inadequate coverage of the cornea is a problem. Its absence indicates a potential postoperative problem if lagophthalmos occurs.

The timing of surgical correction in the absence of significant obstruction of the visual field is often chosen depending on when the parents are motivated and when the child can be adequately evaluated by the surgeon. The child may be about 3 to 4 years of age. Severe ptosis with a significant risk of deprivation amblyopia should be promptly corrected.

Correction of Ptosis

Entire books have been written about ptosis and its correction; therefore it is best to refer to other sources for an in-depth discussion of each of the many techniques, their indications, and the nuances of different approaches. Surgeons who will be treating these patients need to be fa-

miliar with all of the types and degrees of ptosis and able to select and perform the proper ptosis repair for each particular defect.¹⁶⁻²²

The choice of operation is important to ensure optimal correction and symmetry. Generally, these techniques include (1) the Fasanella-Servat procedure¹⁷ (see Fig. 34-5), (2) a resection of Müller's muscle,¹⁶ (3) a levator resection through either an anterior or posterior approach,¹⁸ and (4) a brow suspension with either autologous or alloplastic material¹⁹⁻²³ (see Fig. 34-6).

As stated earlier, the surgical approach depends on the amount of levator function. If good levator function is present (8 to 12 mm), placcation of the levator aponeurosis or excision and repair can be planned. This will usually correct mild to moderate ptosis, and the patient will have little or no lagophthalmos. For congenital ptosis with poor (2 to 4 mm) or fair (5 to 7 mm) levator excursion, a levator shortening or a levator advancement is best. In cases of severe ptosis with minimal or no levator function (less than 2 mm), a frontalis suspension with fascia lata, temporalis fascia, or alloplastic material is the procedure of choice.

A levator aponeurosis advancement is performed by first making a horizontal incision in the lid crease. Scissors are used to dissect through the orbicularis muscle layer and the orbital septum. Once dissection is through the preaponeurotic fat pad, the aponeurotic extension of the levator muscle is identified. This is dissected away from the upper surface of the tarsal plate. After partial resection, the aponeurosis is advanced and sutured to the upper tarsal plate. For each millimeter of ptosis, the levator aponeurosis should be resected 4 mm. As a guide, one plus the amount of preoperative lagophthalmos added to the degree of blepharoptosis should equal the final amount of lagophthalmos in millimeters.²⁴

To perform a Whitnall's sling, after identifying the aponeurosis, Whitnall's ligament in the superior orbit is sutured to the tarsal plate. Nonabsorbable sutures are used. The other approach is to transect the levator muscle just above Whitnall's ligament, advance it over the levator aponeurosis, and suture it to the tarsal plate.^{20,24}

A frontalis suspension elevates the brow by using a sling material to connect the frontalis muscle superior to the brow to the eyelid tarsus. Types of materials used are Gore-Tex,²³ silicone rods, polypropylene suture, and allogeneic fascia lata or autogenous fascia lata.²² Autogenous fascia lata has been reported to have the lowest rate of infection.³ Although some prefer to use alloplastic materials, autogenous tissue even in younger patients can be readily harvested (see Fig. 34-6).

Epicanthus

Epicanthal folds are vertical skin folds in the area of the medial canthus. The skin arches along the side of the nose, with the concavity directed laterally. Most arise from the upper lid above the tarsal region and extend to the lower orbital margin; however, variations occur.^{4,24,25} Epicanthal folds are categorized in four groups: (1) palpebralis, (2) tarsalis, (3) inversus, and (4) supraciliaris. *Epicanthus palpebralis* involves an even distribution of the fold between the upper and lower lids. *Epicanthus tarsalis* refers to the skin fold being greatest in the upper lid. In *epicanthus inversus*, the fold is greatest in the lower eyelid. In *epicanthus supraciliaris*, the fold is between the eyebrow and the lacrimal sac. Congenital epicanthus is most commonly seen in Asians.²⁴ Epicanthal folds may be seen in isolation or associated with syndromes, usually blepharophimosis syndrome (see Fig. 34-4). Although this topic is somewhat arbitrarily separated as a disorder of the soft tissue of the upper lid, cases seen in association with telecanthus and with those having tissue shortages in both the upper and lower lid are reviewed in the discussion of medial canthal deformities.

Fig. 34-7 The Mustardé four-flap technique to correct epicanthal folds. **A**, A mark is made midway between the nasal midline and the center of the pupil. Medial traction is placed on the nose. The medial canthus is marked, and a line is drawn between these points. At the center of this line, two lines are drawn at 60 degrees approximately 1 to 2 mm shorter than the line. Two lines are drawn at 45 degrees, and two paramarginal lines are marked. **B**, The incisions are made, and the flaps are raised. **C**, After the transposition is completed, the flaps are sutured.

Fig. 34-8 Double-opposing Z-plasties for the correction of traumatic epicanthus. **A**, The site is marked. **B**, Incisions are made, and flaps are raised. **C** and **D**, Transosseous wires are secured through the nasal bones, and the flaps are transposed and sutured. Pledgets are tied in place.

Correction of Epicanthus

Epicanthal folds usually resolve with normal development, especially the supraciliaris or palpebralis types. Simple, nonresolving epicanthus is corrected with Z-plasties, one above the canthal angle and another below it. The Mustardé four-flap technique is effective for epicanthus inversus, characterized by an abnormal lower lid fold¹³ (Fig. 34-7). Many surgeons have found that the multiple Z-plasty scars in this region leave residual skin irregularities that make the scar quite visible even though the contour of the canthal area is more normal. For this reason, repairs with fewer Z-plasties than the typical Mustardé four-flap procedure may be preferred in many cases and may result in excellent correction and less visible scars.

Traumatic epicanthus can be corrected with double-opposing Z-plasties (Fig. 34-8). This technique releases the tension and the scar.^{4,7,24} Z-plasties are made opposite each other. After the flaps are raised, the scar tissue is removed. Transosseous wires are placed through the nasal bones. Wires are placed through and through, and the canthal buttons are placed.¹³

DEFORMITIES OF THE LOWER EYELID—SOFT TISSUE**Epiblepharon**

Epiblepharon is characterized by eyelashes that are vertical, because pretarsal muscle and skin overrides the margin of the eyelid, often affecting the lower lids. The lower eyelid may have a congenital absence or deficiency of the adhesion between the lower eyelid retractors and the anterior lamella that allows the skin and muscle to roll upward, accompanied by a hypertrophied orbicularis with an extra skin fold. This condition more often affects Asians and usually resolves spontaneously in the first few years of life.²⁵

Correction of Epiblepharon

Surgical treatment is indicated if epiblepharon does not spontaneously resolve or if the cornea becomes irritated. Repair involves shortening the anterior lid lamella, which is accomplished by excising a horizontal piece of skin with orbicularis muscle. The skin edges are sutured to the eyelid retractors or anterior tarsal surface using absorbable sutures. The deformity can also be corrected by resecting part of the medial canthal tendon and using the Mustardé four-flap technique.^{3,11} When repositioning of the canthal ligament is required, transnasal wires are passed through the end of the medial canthal tendons, and buttons are placed.

Epiblepharon can occur after trauma, burns, and fractures. In these cases, scar tissue may need to be excised, and the inferior part of the lateral canthal tendon may need to be cut to release the tension before transnasal medial canthoplasty.¹¹

Ectropion

Congenital ectropion and oversized eyelids are associated with other lid deformities such as distichiasis and with general congenital abnormalities such as trisomy 21.⁴ Congenital ectropion as an isolated occurrence is unusual and may be confused with euryblepharon. The degree of lower lid soft tissue deficiency varies, as does the degree of exposure of the globe (Figs. 34-9 and 34-10). The tarsal plate, along with the lateral canthal tendon, may be hypoplastic and give little purchase in efforts to use this structure for support. Full-thickness reconstruction of the lower eyelid may be required if the ectropion is severe and cannot be treated by the usual methods of tarsal tightening or skin grafting.

Fig. 34-9 A and B, This 9-year-old girl had congenital ectropion of her upper and lower eyelids. C and D, She is shown after full-thickness postauricular skin grafting to the lower lids and cheeks and a medium-thickness split graft from the upper inner arm to the upper eyelids. (Courtesy of S. Anthony Wolfe, MD.)

Fig. 34-10 Secondary ectropion presents with similar problems of tissue shortages and reconstructive needs in many congenital cases. A, This patient presented with significant bilateral ectropion after a midface lift through the lower eyelids and a second attempt to correct them elsewhere. B and C, Correction entailed releasing the lower lids completely through the previous subciliary incision, excising scar tissue, performing a firm lateral canthopexy with a dermoorbicular pennant flap brought through the lateral orbital wall, and the use of Frost sutures for 1 week and then taping the eyelids for another month. D, The postoperative result without further skin grafting. (Courtesy of S. Anthony Wolfe, MD.)

Correction of Ectropion

Various wedge excisions have been suggested for the treatment of severe ectropion. Tarsorrhaphy sutures are placed to provide corneal protection. Markings are made below the ciliary margins and infiltrated with saline solution and epinephrine. A skin incision over the orbicularis muscle is made, and about a 7 to 8 mm strip of lid margin is deepithelialized and a tarsal strip produced. An incision is made in the upper lid, just beneath the brow in the position where the tarsal crease will eventually be. The periosteum and superior lateral orbital rim are dissected, and a scissor is passed from the supraperiosteal plane down to the tarsal strip area. The conjunctiva and lid margin can be closed with 5-0 plain catgut. A double-armed 4-0 Vicryl suture is taken through the tarsal strip and sutured to the inner lip of the periosteum of the orbital rim (see Fig. 34-10). Tarsorrhaphy sutures are taken between the upper and lower lids. The upper lid incision can be closed with 7-0 silk. The bipediced orbicularis oculi muscle flap is freed and sutured over the tarsal plate with 7-0 Vicryl. A postauricular skin graft is harvested and sutured in place with 7-0 silk, and a tie-over bolus of antibiotic ointment is placed with 6-0 silk. The donor area is closed with 4-0 Monocryl.

Entropion

Congenital entropion is a rare condition in which the eyelid margin is turned inward, and the eyelashes are oriented toward the cornea. It can affect the entire lid. The conjunctiva may become irritated and cause itching, with resultant rubbing of the eyelid. It is theorized that this action causes chronic inflammation and swelling of the orbicularis muscle and overlying skin and soft tissue, accounting for persistent congenital entropion. This frequently results in orbicularis oculi spasm.^{4,24}

Epiblepharon differs from entropion²⁵ in that occasionally the fold of skin in the medial lid may cause some of the lashes to irritate the cornea; for epiblepharon, simple resection of the medial fold of skin will usually cure the problem. An additional difference between congenital entropion and epiblepharon is the positioning of the lid margin in relation to the globe, with the rarer entropion causing more difficulties with trichiasis because of malpositioning of the lower eyelashes.^{26,27}

Ito et al²⁸ described correction of entropion with a horizontal lower eyelid incision below the eyelashes. The pretarsal orbicularis muscle is mobilized with resected excess muscle and skin. If the entropion is more severe, the attached skin is expanded and sutured at the tarsal plate. Once the position of the eyelashes is acceptable, the skin incision is sutured closed.

Distichiasis

Distichiasis refers to an accessory row of lashes along the posterior marginal edges of the lid, occupying the site of the meibomian glands (which they often replace). It varies from trichiasis, in which irregularly placed cilia associated with entropion turn toward the cornea after injury or disease.⁴

Surgical correction involves excising approximately 4 mm of the posterior lamella of the tarsus and conjunctiva, including the posterior row of lashes from the edge of the lid; excision should include all of the abnormally placed follicles. The mucosal defect is grafted with nasal or buccal mucosa. This is preferable to excision and direct closure by tarsoconjunctival advancement, which may result in entropion and recurrent trichiasis. Another procedure involving cryotherapy of the posterior eyelid margin may be performed to destroy these extra lash follicles.⁴

Euryblepharon

Euryblepharon is a widening of the palpebral fissure laterally and vertically caused by a shortage of eyelid tissue. Vertical widening is most prominent laterally. The lateral canthal tendon may be displaced inferiorly, resulting in an antimongoloid slant. Usually, a gutter has formed between the lower lid and the eye.^{4,24}

Topical lubricants are indicated for the management of corneal exposure. If unsuccessful, then surgical repair is necessary. Congenital ectropion treatment, as for acquired ectropion, may need to include full-thickness skin reconstruction, a lateral canthopexy, and a tarsal strip procedure or full-thickness lid reconstruction.^{26,28}

Euryblepharon is sometimes seen in patients with Apert syndrome. It may be improved by advancement of the bony orbit and reduction of the prominence of the globe to the extent that it is less likely to push the eyelids to a wide open position.

Ankyloblepharon and Cryptophthalmos

Ankyloblepharon is fusion or incomplete separation of the upper and lower eyelids. This condition may be inherited in an autosomal dominant manner. Fusion can be lateral or medial.²⁴ Ankyloblepharon filiform adnatum consists of many tissue strands between the upper and lower eyelids. This may be associated with central nervous system, cardiac, and ectodermal findings.²⁹

The treatment of ankyloblepharon is surgical. The eyelids are separated, with careful attention to the medial aspect to identify the lacrimal ducts.³

Cryptophthalmos is a failure of normal embryonic development of the lid fold (epithelium), which normally differentiates into the cornea and conjunctiva. The lid folds fail to develop, and the eye is buried in the developing cover of the epithelium but does not differentiate normally. Cryptophthalmos is inherited as an autosomal recessive congenital defect. It may be associated with syndactyly and other congenital defects, including cardiac, facial, ear, and cortical developmental defects (Fig. 34-11).

Fig. 34-11 A, This patient had congenital cryptophthalmia. She is shown before reconstruction of the eyebrow and full-thickness skin grafting to the upper and lower lids and eyelash grafting to the upper eyelids and brow. An ocular prosthesis was placed. B, The postoperative result. (Courtesy of Paul Tessier, MD.)

Because the eye does not differentiate normally, surgery will not successfully expose and preserve the globe.

MEDIAL CANTHAL DEFORMITIES

Medial Canthal Dystopia

Malposition of the medial canthal tendon is rarely an isolated finding, but it occurs with naso-ocular clefting. To correct the downward displacement of the medial canthal tendon, the tendon must be freed of all periosteal attachments and replaced upward to attach to the lacrimal bone in a more normal position. This reconstruction may best be done in concert with additional craniofacial procedures performed to treat the complex skeletal and soft tissue deformities inherent in the surface and underlying bony clefts.⁴

Telecanthus and Blepharophimosis Syndrome

Telecanthus alone is known as *Waardenburg syndrome*.⁴ Telecanthus in association with epicanthus inversus, decreased horizontal lid fissure, and ptosis is known as *congenital tetrad syndrome* or *blepharophimosis syndrome* and is an autosomal dominant disorder. In blepharophimosis syndrome, the eyebrows appear arched from the ptosis.²²⁻²⁴ Other findings include ectropion of the lower lid, flattening of the nasal bridge, and hypoplasia of the superior orbital rim. Usually, the supratarsal fold of the upper lid is absent. Forehead and/or ear deformities may be present. The neck may be extended, allowing the patient to see below his or her ptotic eyelids.²⁴ Patients with type I blepharophimosis have blepharophimosis with epicanthus inversus and ptosis. The findings in type II include telecanthus, ptosis, ectropion of the lower lids, absent epicanthal folds, and an insufficient amount of skin in all lids. Type III is characterized by telecanthus, ptosis, hypertelorism, slanting palpebral fissures, and an insufficient amount of eyelid skin.¹³

Correction of Telecanthus and Blepharophimosis Syndrome

Surgical correction is often performed by the time a patient is 3 to 5 years of age, after the nose and midface are able to grow.²²⁻²⁴ For those with type I blepharophimosis, the quadrilateral flap technique described by Mustardé or a Z-plasty (double-opposing) is used.¹³ A bony window can be created through the lacrimal groove. Medial canthal tendons are transnasally wired and advanced into the window (Fig. 34-12). The severe ptosis is often corrected by suspension of the frontalis muscle. Type II correction involves correcting the deficient skin with skin grafts. Medial canthal tendons are fixated into the medial orbits and by transnasal wiring (see Figs. 34-4 and 34-12). Other modes of treatment may involve medial translocation of the medial orbital walls and transnasal wiring of the medial canthi. Ptosis is corrected by frontalis suspension or other techniques. Correction of type III involves skin grafting of the eyelids and medial canthoplasty. Hypertelorism is corrected by moving the orbits medially. Ptosis is also corrected in this manner.^{13,19,22,23}

FACIAL CLEFTS—COMBINED BONE AND SOFT TISSUE DEFECTS

Although combined skeletal and soft tissue eyelid defects are discussed in Chapter 26, we will present some additional defects in this chapter. As noted previously, colobomas of the medial and lateral lower eyelid and medial upper eyelid can be associated with incomplete facial clefts. They manifest mostly as a soft tissue deformity; however, in general, they are associated with an underlying bony cleft.^{5,6,30-34}

Tessier Classification

In 1976 Paul Tessier⁵ published his classification of facial clefts.⁶ He designed this to be an orbitocentric classification, with the clefts passing like time zones through the orbit. Clefts that involve the lower eyelid include Tessier 3, 4, 5, and 6 (Figs. 34-13 through 34-18). In addition to his enormous contributions—which have resulted in the new field of craniofacial surgery—and the Tessier cleft classification, Paul Tessier was an orbital and eyelid surgeon without equal. The literature includes many examples of complex and sophisticated bony reconstructive procedures in the periorbital area that left residual soft tissue deformities uncorrected, allowing the stigmata of the defect to persist. Tessier's cases, illustrated in the following section, clearly demonstrate his results as the benchmark. It is highly unlikely that another surgeon will have his vision, experience, and technical ability.

Fig. 34-13 Tessier's classification of facial clefts, designed as an orbi-centric classification with the clefts passing like time zones through the orbit, showing underlying skeletal defects and soft tissue clefts.

Fig. 34-17 A and B, Bilateral Tessier number 3 oroocular clefts in full-face and close-up views at birth. C and D, Similar views at 8 years of age. (Courtesy of S. Anthony Wolfe, MD.)

Fig. 34-18 A, This child was born with a soft tissue mass growing from the sclera in association with a Tessier number 6 cleft. B, Postoperative appearance. (Courtesy of S. Anthony Wolfe, MD.)

Fig. 34-19 A and B, This 8-year-old girl had Treacher Collins–Franceschetti syndrome. C and D, The patient is shown after reconstruction of the zygomatic arches with cranial bone, lateral canthopexies, and, at a later stage, a fat dermal graft to the malar area and a genioplasty. (Courtesy of S. Anthony Wolfe, MD.)

Treacher Collins syndrome, also known as *Franceschetti complex*, is a maxillary-zygomatic cleft with a coloboma of the lower eyelid, between the middle and lateral thirds. The cleft is between the maxilla and zygomatic bone, opening into the infraorbital fissure. The cheek area has a further furrow or cleft angling downward. This is a Tessier number 6 cleft. The Tessier number 7 cleft is a temporozygomatic cleft with absence of the zygomatic arch and deformities of the mandible (Fig. 34-19; see Fig. 34-2). The sporadic form of this defect is seen in hemifacial microsomia and in varying asymmetrical degrees in Goldenhar syndrome. In the lateral views of this patient, both ear anomalies and soft tissue deficiency are visible. The deformities are discussed in detail in Chapter 30.

Amniotic Bands

Ocular and oroocular clefts related to amniotic band disruption during facial development present with all of the complexity of soft tissue and bony deformity seen in the group of Tessier clefts discussed previously, but they do not fit into the traditional cleft trajectories. These can be seen alone or in combination with more typical clefts because of the disrupting effect of the encircling amniotic band on the normal developmental processes.³⁵ Fig. 34-20 shows a patient with amniotic bands, a cleft lip, and right microphthalmos before and after multiple reconstructive procedures, including transcranial elevation of the left orbit, reconstruction of the right orbit and right socket, nasal bone grafting, a LeFort type I osteotomy, and a sagittal split of the mandible. Despite multiple procedures, these reconstructions can fall short of an ideal outcome.

Socket Deformities—Combined Bone and Soft Tissue

Microblepharon and Ablepharon

Development and growth of the globe is the primary stimulant for growth and development of the bony orbit. If the eye does not develop, the bony orbit will not develop, resulting in asymmetry of the orbits and possibly soft tissue hypoplasia. In these cases of microblepharon or ablepharon, the usefulness of the globe or remnant must be evaluated before beginning treatment.

Fig. 34-20 A, This child was born with oroocular clefting caused by amniotic band disruption, a cleft lip, and right microphthalmos. B-E, The patient is seen at 1, 2, and 19 years of age, before and after multiple reconstructive procedures, including transcranial elevation of the orbit, reconstruction of a right orbit and right socket, a nasal bone graft, a LeFort type I osteotomy, and a sagittal split of the mandible. (Courtesy of S. Anthony Wolfe, MD.)

Microblepharon is a rare, full-thickness shortening of eyelid tissue often with absent eyelashes and eyebrows and nearly always with severe hypoplasia of the globe. It is usually unilateral. Management is determined by the visual acuity of the small eye. Ablepharon is more extreme, with aplasia of the globe.^{4,29}

Anophthalmos and Microphthalmos

Clinical anophthalmos is the term used by Duke-Elder³ to denote most of the cases in which the eye appears to be absent, although such a socket may contain an extremely small microphthalmic eye (see Fig. 34-11). The lids are variably hypoplastic with a short palpebral fissure and small socket.^{4,36}

The following four factors are critical in the treatment of the hypoplastic orbit and lids:

1. If the orbit is hypoplastic, expansion with progressively larger, expanding orbital implants must be carried out and continued through the period of normal orbital growth.
2. Expansion is more easily obtained by starting earlier than by starting later.

3. The soft tissue of the orbit often requires reconstruction to facilitate the use of an ocular prosthesis.
4. The decision to remove the remains of a poorly developed eye should be made by an ophthalmologist because of other factors related to the globe.

TUMORS AND CYSTS

Dermoid Cysts

Dermoid cysts are hamartomas consisting of ectodermal elements. They typically present as collagenous tissue containing hair follicles and sebaceous and sweat glands and are usually covered with keratinized epithelium. In most cases, dermoid cysts are fixed to the orbital rim periosteum at the frontozygomatic suture (so-called external angular dermoids) but can be loosely attached, allowing them to drift down onto the lid (Fig. 34-21). They may sit in a deep trough in the orbital rim. Rarely, they are intraosseous (see Fig. 34-21, *F*). With the exception of rare intraosseous cysts (which may erode intracranially), they do not extend intracranially.³⁷ It is not clear why this pattern is so common, but it is of interest that they lie along the trajectory of the Tessier number 10 cleft. They may also present more medially along the brow and supraorbital rim. Once they approach the frontonasal junction, they should be evaluated in the same way as a frontonasal dermoid (which may follow well-described paths of intracranial extension).

Fig. 34-21 A, A typical position for an external angular dermoid cyst. B, Unusual bilateral cysts before excision. C-E, The cyst in this patient contains well-developed hairs. On excision, the trough in the underlying bone is visible. F, An axial CT view of another patient shows a rare intraosseous dermoid in the bone of the left lateral orbit. (Courtesy of S. Anthony Wolfe, MD.)

Dermoid cysts may grow slowly and rarely reach 4 cm in size. Those in closer contact with the bone may deform it further as they expand. They can become inflamed and rarely infected. Some fluctuate in size, and this may relate to varying activity of the sweat glands present. From a timing standpoint, little is gained in waiting for the cysts to potentially grow larger, and excision any time after a patient has reached 6 months of age, when the anesthesia risk is lower, makes these cases very uncomplicated.³⁷

Most external angular dermoids (see Figs. 34-21, *A* through *E*) can best be excised through an incision in a lid fold of the upper outer eyelid. Dermoids always lie deep to the orbicularis muscle. Those that drift higher toward the temporal region (more than half the distance to the hairline) can be approached through a hairline incision. Endoscopic-assisted excision has been suggested, but this has been associated with injury to the temporal branch of the facial nerve and is therefore discouraged.

Hemangiomas

Hemangiomas are benign vascular tumors with a triphasic growth cycle: proliferation, cessation of growth, and involution. They may present as superficial “strawberry” lesions, deep lesions within the subcutaneous tissue and orbit, or a combination of both. They can be present at birth or develop postnatally, when a small, reddish lesion (herald spot) expands into a much larger growth. Although many hemangiomas will involute without residual tissue, those typically seen by plastic surgeons tend to result in some degree of residual scarring, subcutaneous fibrofatty excess, and associated lid laxity^{4,38} (Figs. 34-22 and 34-23).

Hemangiomas of the eyelid (particularly the upper eyelid) and orbit present one of the true emergencies in the treatment of orbital lesions.^{4,38-40} Early treatment is directed toward preserving vision and preventing the associated amblyopia seen with bulky hemangiomas of the eyelids.⁴⁰ Treatment may involve systemic steroids alone, intralesional injection of combined fast- and slow-acting corticosteroids, or, very rarely, surgery. Some authors report the most effective treatment to be intralesional injection of steroids.²⁴ A combination of short- and long-acting corticosteroids such as betamethasone 0.5 to 1 mg/kg and triamcinolone 3 to 5 mg/kg can be injected with the greatest result at 2 to 4 weeks. Repeat injections are usually needed at 4 to 8 weeks.^{38,39} Although rare, complications of such therapy include deposteroid embolization from injection into the arterial channels of the hemangioma, Cushing syndrome, adrenal suppression, eyelid necrosis, and fat atrophy. Before and after treatment, surgeons should evaluate the retinal vessels for central retinal artery occlusion.⁴¹ Historically, systemic steroids, alpha interferon, and vincristine were used for treating rapid, uncontrolled growth of a hemangioma. Propranolol is currently the drug of choice for hemangiomas with rapid, uncontrolled growth and those whose growth places critical structures at risk, for example, the nose, lips, or ears.

Residual surface vascular changes, scarring, and excess fibrofatty tissue may distort the eyelid and brow. Procedures should be staged to improve contour and correct ptosis of the upper lid and to prevent overexcision that may result in exposure problems and ectropion of the lower lid (see Figs. 34-22 and 34-23). Procedures may be spaced over many years. They typically decrease in the degree of complexity, but minor revisions may be needed in a patient's adult years as age-related changes affect the normal areas and areas previously involved by the hemangioma. When residual vascular changes are noted in skin that cannot be resected without the risk of lagophthalmos or ectropion, the use of a tunable dye laser should be considered.^{4,38}

Fig. 34-22 A and B, This 3-year-old was treated with oral steroids and no other intervention during the proliferative phase of her hemangioma. Despite the size and obstructive nature she was spared visual problems. With constant manual lifting of the hemangioma she could see. C, At 3½ years of age, she had debulking with limited skin resection above the lid fold and in the medial canthal area, with partial correction of ptosis and definition of her lid fold. D and E, She is shown at 4 years of age, before and immediately after her second-stage debulking with limited skin excision. F, Immediately after a third-stage reduction at 4½ years of age. G, At 6 years of age. H, At 8 years of age, 2 years after the stage-three reduction, only fine telangiectatic vessels are visible and lid symmetry is good.

Fig. 34-23 A, At 11 months of age, this girl had extensive involvement of her face despite early systemic steroids and injection of the upper eyelid with combined rapid- and slow-acting steroids. B, At 31 months of age, improvement was substantial. C, At 4 years of age, after the first debulking. D, At 5½ years of age, 1 year after her first surgery. E-G, She is shown at 7, 8, and 9 years of age, after continued reduction of excess skin and residual hemangioma. H and I, Two views of her face show good symmetry of the lids and substantial improvement of all residual facial scars.

Vascular Malformations

Vascular malformations are hamartomas with abnormal collections of capillaries, veins, lymphatics, or combinations of several of these.^{4,38} They are present at birth but not always visible at that time. They can grow slowly over the years, and they do not involute. They may be low flow (most commonly) or high flow. These lesions are discussed in depth in Chapter 11. When the extent or nature of the lesion is in question, preoperative imaging should be ordered. This may involve CT, MRI, MRA, or angiography.

Capillary malformations associated with Sturge-Weber syndrome are worthy of note³⁸ (Fig. 34-24). They present with capillary vascular malformation most typically in the upper two divisions of the trigeminal nerve distribution and are often unilateral but may be asymmetrically bilateral. They are associated with intracranial calcifications and seizure disorders. Early treatment with a laser can significantly decrease the prominence of the surface capillary malformation. Whether this affects later soft tissue hypertrophy is not known. Infants with portwine stains should be followed by an ophthalmologist every 6 months until they are 3 years of age and then every year afterward.⁷

Superficial vascular malformations can be treated with laser therapy, whereas deeper venous malformations may require either sclerosis or surgery (Fig. 34-25). Lymphatic malformations and arteriovenous communications affecting the orbit and eyelid can be treated with surgery, sclerotherapy, and/or embolization.⁷

Fig. 34-24 **A**, This patient had a Sturge-Weber malformation involving the right side of his face. He had seizures associated with this condition and multiple calcifications of the dura of the right frontal lobe and a congenital glaucoma of his right eye. **B**, He is shown at the early stages of his reconstruction, with the noninvolved skin of his left forehead used for his nasal resurfacing. A portion of the forehead flap with the hair-bearing scalp was used for his right brow. His upper lid was resurfaced with a medium-thickness graft from his upper inner arm. His cheek and temporal area were resurfaced with a deltopectoral flap, which was initially attached behind his right ear. The patient did not want to have further reconstruction beyond this stage. In addition, follow-up is no longer possible. (Courtesy of S. Anthony Wolfe, MD.)

E and F, The frontal and submental views after the malformation was approached transcranially and the orbital roof removed to provide access to the mass in the superomedial portion of the orbit. The mass was removed in continuity with the orbital floor portion by careful bipolar cauterization of all vessels. (Courtesy of S. Anthony Wolfe, MD.)

Neurofibromatosis

Orbitopalpebral involvement is common in type I neurofibromatosis. A spectrum of deformity exists, ranging from a small, isolated neurofibroma in the eyelid to conditions of such severe deformation that orbital exenteration is the best solution. Optic nerve gliomas, enlargement of the superior orbital fissure, and major defects of the orbital roof with intracranial extension of plexiform neurofibromas may also occur.⁴

Neurofibromas pose a surgical challenge, because they are often vascular and infiltrative with nondistinct borders. Although an en bloc total excision is preferable to debulking, it is rarely possible. The most common form of orbitopalpebral plexiform neurofibromatosis involves an insidious growth with gradual skin changes, loss of skin and supporting tissue elasticity, and ongoing orbital changes. The patient and surgeon should expect that a number of procedures, at times radical, may be required. Rarely is all abnormal tissue removed, and what is not is expected to regrow (though possibly to a lesser extent) (Figs. 34-26 through 34-28).

Fig. 34-27 A, This young Cuban child presented to Drs. Paul Tessier and Henry Kawamoto with orbital palpebral neurofibromatosis and was operated on in Havana. B, A transcranial approach was used. A new orbital floor was made out of iliac bone, and the orbital roof was reconstructed with iliac bone. No further follow-up is available. (Courtesy of Paul Tessier, MD.)

Fig. 34-28 A, This young girl presented with orbitopalpebral neurofibromatosis beyond the stage at which reconstruction was thought to be worthwhile. B and C, The eyelid and orbital contents were amputated, and she uses a patch. (Courtesy of S. Anthony Wolfe, MD.)

Congenital Melanocytic Nevi

Congenital melanocytic nevi of the eyelid are uncommon and may present confined to the eyelid alone or as part of a more extensive nevus of the periorbital region, hemiface, or bilateral face. These lesions may be confined to a single lid or present as a synchronous lesion (a so-called divided nevus). The previously described embryology of the eye and eyelids helps to explain the pathogenesis of the divided nevus, because the migration or differentiation of melanocytic cells seems to occur while the eyelids are fused. When the eyelid's open, the nevus appears divided.⁴

The risk of malignant transformation in giant congenital nevi is well established. The risk of malignant transformation in congenital facial nevi appears to be less common; however, the psychological impact on a child with a pigmented facial nevus and his or her family can be profound.

Additionally, eyelid nevi can produce a variety of functional problems. Ptosis may occur as a result of heavy nevus burden on the upper lid. Exophytic growth can produce warty excrescences that cause redundancy in the lower lid with resultant ectropion. Ciliary growth can become disorderly and lead to chronic corneal irritation. For all of these reasons, excision and reconstruction of these nevi seem indicated.

The timing and staging of the excisions vary depending on the extent of the nevus, whether the contiguous nevus needs treatment as well, and the surgeon's comfort in performing the varied flaps and grafts needed. Unlike the excision of malignant tumors of the eyelid, the excision is confined to the skin and subcutaneous tissue; therefore the surgeon must balance the risk of functional problems associated with complete excision, including the full ciliary margin of the lid, with the limited aesthetic deformity associated with a thin residual strip of nevus on an otherwise normal lid margin. If functional issues are involved, the surgeon may decide to resect and reconstruct the full lid margin (Figs. 34-29 and 34-30).

Fig. 34-29 **A**, This child presented with congenital nevus involving the medial upper and lower eyelid, the canthus, and the medial half of the brow. **B**, The lesion was excised in a single stage and included nevus of the brow. **C**, The medial lower eyelid was reconstructed by advancing a lower eyelid flap, the upper eyelid and canthal area were reconstructed with a postauricular full-thickness skin graft, and the brow was reconstructed with an island flap from the temporal scalp. **D**, The patient is shown 7 years postoperatively, just before the brow was thinned.

22 years after excision and reconstruction

3 weeks after brow suspension and scar revision

Fig. 34-29, cont'd E, Seventeen years after the thinning of the brow and 22 years after the nevus excision, the graft of the lids is barely perceptible. The brow hair density is quite similar to that of the normal brow, although the normal, medial brow appears ptotic compared with the reconstructed side. F and G, He is shown 3 weeks after elevation and suspension of the left brow and revision of the scar of the lateral eyelid. His lid shape, position, and symmetry are excellent.

Fig. 34-30 This case presents the use of expansion to allow harvest of a full-thickness skin graft from an expanded supraclavicular donor site to cover the eyelids and periorbital area in a single unit. A portion of the expanded forehead flap was used to cover the nasal dorsum after a nevus excision. A, This baby girl presented at 10 months of age with a giant nevus of the forehead, periorbital area, eyelids, and nasal dorsum. Two expanders were placed (250 cc in the forehead and 70 cc in the supraclavicular area). The expanded forehead flap was used to reconstruct the involved forehead and the nasal dorsum. A full-thickness skin graft from the expanded supraclavicular donor site was used to reconstruct the remaining periorbital region. B, The patient is shown after 9 weeks of expansion of the forehead. C, Following a pattern of the lids and the periorbital area, a full-thickness graft was harvested off of the dome of the expander, the capsule was excised, and the donor site was closed. In addition, the nevus was excised, sparing the lid margin and ciliary border and eyebrow. The graft was sutured in place in a single unit. D, The patient is shown 9 years after the excision and reconstruction.

Acquired Deformities of the Eyelid

ACQUIRED LESIONS OF THE EYELID

Relatively few acquired lesions and cysts of the eyelids are seen in children. (Most are discussed in Chapter 8.) Chalazion lesions are one of the few types unique to the eyelids.

Chalazion

A chalazion results from obstruction of the eyelid meibomian glands. Sebum accumulates and instigates an inflammatory response. A chalazion may subsequently become infected.³ Treatment involves the use of warm compresses. Topical corticosteroids and antibiotics may be indicated. If a lesion persists, incision and drainage are indicated. Recurrence is reduced with the injection of corticosteroids afterward.²⁴

POSTTRAUMATIC DEFECTS OF THE EYELIDS

Preoperative Assessment and General Principles

In a trauma patient, visual acuity and ocular motility and the condition of the cornea should be evaluated. For all but the simplest of lacerations, having all patients evaluated by an ophthalmologist is probably prudent. The eyelids require careful evaluation for any foreign bodies and debris. Lacerations involving the eyelid skin with or without the orbicularis muscle are considered superficial. Surgeons should document whether the levator muscle and orbital septum are intact.¹¹

When trauma to the canthus and canalicular system has occurred, the presence of traumatic telecanthus and possible division of the lacrimal duct system is documented. In cases of severe trauma, the globe must be protected with adequate lubrication before and during the reconstruction.

Whether treatment involves limited lacerations of the lid margin or more significant defects, meticulous approximation of the key lid structures is essential to limit secondary defects. Traumatic avulsions of the eyelid from dog bites, human bites, and other accidents require suture approximation and can be successful even 28 hours after the injury. If the tissue loss is severe or tissue has been completely destroyed, there is risk of corneal exposure and subsequent keratinization with vision loss. The risk is greatest when the upper lid is involved, because the upper lid provides the greatest corneal protection.

Eyelid margin laceration repairs are reassessed in 24 hours. The skin sutures are removed after 3 to 4 days. Steri-Strips are applied. Marginal sutures remain in place for 1 week. When the eyelid has been destroyed, repeated observation is necessary to assess for corneal changes. Lubrication is essential during the healing process and until the globe is adequately protected with the varied reconstructive maneuvers.^{9,42-45}

Basic Surgical Principles in Eyelid Reconstruction

Intraoperatively, the eye should be protected by frequently applying lubricants or a balanced saline solution onto the cornea or in the conjunctival cul-de-sac. This is done using a plastic protective corneal lens and retractors or malleables to protect the eye from sharp instruments. Surgeons should select sutures that will prevent corneal irritation. If the eyelid margin is involved, precise alignment is required with appropriate tension. Therefore the use of loupes or other magnifying devices is strongly recommended. Wound edges may be trimmed slightly to freshen them.^{4,9,43-45}

Fig. 34-31 Repair of a full-thickness lower eyelid defect (detail). The conjunctival layer is closed with a rapidly dissolving suture such as 6-0 plain catgut or 7-0 Vicryl. Key sutures are then placed: a 6-0 silk suture at precisely the same level in the gray line, just behind the lash line and a 6-0 Vicryl suture through the tarsal plates.

Fig. 34-32 A, A defect involving less than 25% of the eyelid in a child or up to 30% in an adult can be closed by primary repair. B, After the repair.

Upper and Lower Eyelid Defects

Defects of Less Than Twenty-five Percent

A loss of up to 25% of either the upper or lower eyelid can be closed by direct approximation; the figure increases to 30% or more in older patients with some lid laxity (Figs. 34-31 and 34-32). To repair a full-thickness eyelid defect, the tarsal plate should be closed with 6-0 Vicryl as a separate layer, the conjunctival layer with 6-0 plain catgut or 7-0 Vicryl, and the skin with 6-0 silk. The gray line, just posterior to the lashes, should be carefully aligned with 6-0 silk.

Upper Lid Defects of Greater Than Twenty-five Percent

A lateral canthotomy makes it possible to close up to about 40% of the eyelid in combination with the direct closure noted previously (Fig. 34-33). Adding an extension into the temporal area beyond the lateral canthus with a limited rotation flap (Tenzel) (Fig. 34-34) or all the way to the preauricular area (Mustardé) (Fig. 34-35, A) facilitates reconstruction of the outer lamella of the entire lower eyelid. The inner lamella will need to be reconstructed with a rigid mucosa-covered graft, either a split palatal or a septal chondromucosal graft (Fig. 34-35, B and C).

Fig. 34-33 A lateral canthotomy is added if tension on a primary closure seems excessive; this will allow closure of a defect of up to 40% of the lower eyelid.

Fig. 34-34 If a lateral canthotomy does not provide enough laxity, the next step is a Tenzel flap, a short rotation flap that does not extend much beyond the lateral rim. Here, a small chondromucosal flap is added for the inner lamella; this can be from the nasal septum, the upper lateral nasal cartilage, or a split palatal graft. (Mucosal grafts alone are not used, because they undergo considerable contraction.)

Fig. 34-35 **A**, A full-thickness defect of the entire lower eyelid can be repaired by a Mustardé cheek rotation flap extending to the preauricular area with a cutback. **B** and **C**, This flap relies on a very sturdy septal chondromucosal graft to support the lower eyelid. Its vascularity can be questionable, and it is not our first choice for total lower eyelid reconstruction.

A Mustardé-type cheek rotation flap can be used for total lower lid reconstruction, but we prefer a Tessier nasojugal flap (Fig. 34-36) because of its greater vascularity and support; Mustardé flaps tend to require the rigidity of a thick septal chondromucosal flap to prevent sagging.

Another alternative for defects of most of the lower eyelid is a Kolner procedure (Figs. 34-37 and 34-38). A tarsoconjunctival flap can be taken from the upper lid to reconstruct the defect.

Fig. 34-36 A, Our preferred flap for total lower eyelid reconstruction is a Tessier nasojugal flap. The base of the flap should be slightly higher than the medial canthus, and the tip should be fixed firmly to the periosteum of the lateral orbital rim. B, A chondromucosal or split palatal graft is used for the inner lamella.

Fig. 34-37 A, For marginal defects of the lower eyelid with a vertical dimension of 10 to 12 mm or less, a tarsoconjunctival flap from the upper eyelid is an excellent alternative. B, The upper eyelid is everted, and an incision is made 4 mm from the lid margin, through the tarsus, to a transverse dimension matching the defect of the lower eyelid. Superiorly, the flap is teased from the overlying levator muscle and contains conjunctiva and Müller's muscle. The dissection should be taken well into the superior cul-de-sac to prevent tension on the upper eyelid when it is sutured into the defect. C, The tarsus of the flap and the remaining native tarsus should be carefully reapproximated. D, A full-thickness skin graft is taken from the preauricular or postauricular area to replace the anterior lamella. (We prefer not to use upper eyelid skin, because it is too thin.) The pedicle of the flap is divided at about 3 weeks, with care to bring the conjunctiva over the lid margin. The donor area will heal spontaneously.

Fig. 34-38 A, This patient presented with an extensive basal cell carcinoma of the lower eyelid and adjacent cheek. B, Resection required removal of the patient's entire lower eyelid and a good portion of his cheek. Reconstruction was divided into two separate segments: the lower eyelid and the cheek. C, A tarsoconjunctival flap was brought from the upper lid and sutured to the remnants of the conjunctiva, carrying with it some tarsus. D, This was covered with a full-thickness graft, and the cheek defect was corrected with the use of a rotation cheek flap. E, The postoperative result. (Courtesy of S. Anthony Wolfe, MD.)

The tarsus is split 3 mm superior to the ciliary margin, the length of the lower eyelid defect. The conjunctiva and Müller's muscle are bluntly dissected from the overlying levator muscle well up into the conjunctival cul-de-sac. The tarsus is sutured to the tarsal remnants of the lower eyelid, and the outer lamella is reconstructed with a full-thickness skin graft.

Upper Lid Defects of Greater Than Fifty Percent

Larger upper eyelid defects require reconstruction, which may involve a selective lateral cantholysis of the lateral canthal superior crus and medial transposition of the upper lid. A lateral cantholysis is recommended to facilitate closure of these wounds, especially those with loss of tissue in the middle portion of either lid. This method releases the tension that would be present with direct closure. Scissors are used to perform a lateral canthotomy. The conjunctiva is separated from the lateral canthal tendon, and a vertical incision is made into the upper or lower crus (depending on the defect). This maneuver may provide 5 to 10 mm of horizontal length. A local skin flap may also be needed. Defects as large as 60% of the horizontal length might necessitate lid-switch procedures. Tissue can be borrowed from the lower lid, whose blood supply is the marginal palpebral artery (Fig. 34-39). These flaps can be 25% narrower than the width of the defect and should be 5 to 6 mm in height to preserve the blood supply. Larger defects (60% to 100% of the length) are often reconstructed using a Cutler-Beard flap or a Mustardé total lid flap. Both are two-stage operations. A Cutler-Beard flap involves creating a full-thickness lower lid flap. The flap is advanced under the margin of the lower lid to correct the upper lid defect. A Mustardé lower lid flap involves a full-thickness lid switch flap and lateral canthotomy. Although the resultant lower lid defect can be corrected with a graft and cheek advancement flap, we prefer to reconstruct the lower eyelid with a Tessier nasojugal flap (Figs. 34-40 and 34-41).

Fig. 34-39 For a partial-thickness defect of the upper lid, either a coloboma or a traumatic defect, the lower lid is the preferred donor area. A Mustardé-Abbé type flap can be based on a very small marginal pedicle; the flap from the lower lid is designed to be a bit smaller than the upper lid defect (a defect of about 20% of the upper lid could be closed primarily). The pedicle is divided at about 3 weeks, with a careful alignment of both lid margins.

Fig. 34-40 For a total reconstruction of the upper eyelid, it is best to use the entire lower eyelid, if one is available. **A**, A resection of a tumor involving the entire upper eyelid. The lower eyelid, based laterally, is folded over on itself with its medial margin sutured to the lateral canthus. **B-D**, A chondromucosal or split palatal graft is used for the inner lamella of the lower eyelid, and a Tessier nasojugal flap is used for the outer lamella. **E**, After a month, the lateral pedicle of the lower eyelid flap (now the upper eyelid) is divided and sutured to the medial canthal area. The levator muscle, if present, should be sewn to the tarsus of the flap.

Fig. 34-41 This case describes a total reconstruction of the upper eyelid using the entire lower eyelid, with a nasojugal flap with a buccal graft for reconstruction of the now-absent lower eyelid. **A**, The upper eyelid defect is visualized and the nasojugal and Mustardé flaps outlined. **B**, The lower lid flap is reflected. **C and D**, The buccal graft is placed. **E**, The nasojugal flap is positioned for external coverage of the lower eyelid, and the Mustardé flap is rotated upward into the upper eyelid defect.

Fig. 34-41, cont'd F, The Mustardé flap is inset, completing the first stage of the reconstruction. G, The flaps are shown 3 weeks after the first stage but before division of the Mustardé flap and inset. H-J, Division and inset of the medial portion of the new upper eyelid. K, Reflection of the completely reconstructed upper eyelid at the completion of the second stage. (Courtesy of Paul Tessier, MD; photos provided by S. Anthony Wolfe, MD.)

Other techniques include a glabellar or nasolabial flap with mucosal or composite grafts. The upper eyelid is essential to protect the cornea. Therefore lower lid reconstruction does not borrow tissue from the upper lid. Tissue may be borrowed from the contralateral lower lid or other areas such as the cheek.^{7,45}

For reconstruction of both eyelids, a very large split palatal graft is sutured to the remnants of the conjunctiva, and the entire defect is covered with a distant flap (posterior forehead, if available), with a small opening medially for drainage. The flap can then be debulked and replaced with medium split (upper lid) and full-thickness skin grafts (lower lid) before division into two eyelids. Movement may be minimal if there is no levator, but if a functioning Bell's phenomenon is present, the eye will be protected and can be of use (Fig. 34-42).

Fig. 34-42 A, This young boy was involved in an automobile accident in South America and had avulsion of both eyelids, much of his nose, and most of his forehead. B, As an emergency procedure, an ear, nose, and throat surgeon placed a pectoralis flap over the entire eye. C and D, The boy is shown after replacement of the pectoralis flap to the chest, a tissue expander to the cheek, a Tagliacozzi flap for the nose (the forehead was not usable), and multiple split-thickness skin grafts of varying thickness for the eyelids. He has minimal levator function but has protective corneal covering and normal vision in his eye. The arm flap is a poor color match for his face but can be resurfaced with a thin split-thickness skin graft, which usually provides a near-perfect color match. (Courtesy of S. Anthony Wolfe, MD.)

Treatment of Secondary Posttraumatic Deformities of the Eyelids

Posttraumatic Telecanthus

There is no better time to correct disruption of the medial canthal tendon than at the initial repair. More extensive trauma to the periorbital tissues and orbit can involve soft tissue and bone. In these cases, obtaining an ideal correction—particularly for unilateral cases—is challenging (Figs. 34-43 through 34-45). The treatment of telecanthus associated with more extensive maxillofacial trauma is discussed in Chapter 40. The actual maneuvers of fixation are similar to those demonstrated earlier in our discussion of the repair of ocular clefts.^{9,42,45} A few additional comments are in order here and pertain to secondary correction.

Fig. 34-43 A, This 3-year-old boy was badly mauled by a pit bull. The medial canthal tendons were avulsed through the laceration in the forehead. B, These were sutured back in position to the periosteum at the primary repair, but this did not heal. C-E, The patient is shown postoperatively after bilateral transnasal medial canthopexies, in which the transnasal wires were tied over a 2 mm miniplate. Lead plates are tied over an Adaptic dressing to compress the skin above the medial canthal tendon. (Courtesy of S. Anthony Wolfe, MD.)

Fig. 34-44 A transnasal medial canthopexy showing the fine details of the passage of the nasal trocar and fixation of the ligament. In the case presented in Fig. 34-43, the procedure was performed for a patient with unilateral nasal agenesis. **A**, The medial canthal tendon is identified and divided from its abnormal attachment. The orbital septal attachments to the upper and lower orbital rims must be extensively divided. **B**, A transnasal hole is prepared with a Tessier canthopexy awl (similar to an ice pick, but with a cutting tip). The *inset* shows the suture. **C**, A canthopexy suture of 2-0 or 3-0 stainless steel wire is then passed through the hole (retrieved with a loop from the contralateral side) and tied over a two-hole titanium miniplate as a toggle.

Excellent results are virtually never obtained, particularly if they are compared with a normal canthus on the contralateral side. A good result requires extensive subperiosteal dissection of the orbital septal attachments and careful identification of the medial canthal tendon through a skin incision made close to the tendon. A wire suture is passed twice through the tendon, passed through a transnasal hole, and tightened over a two-hole miniplate on the contralateral side. Additional transnasal wires above the medial canthopexy can be passed by placing a spinal needle on a K-wire driver and then passing a transnasal wire; this is done twice, and the wires are tightened over Adaptic pledgets (see Figs. 34-43 through 34-45). This helps to prevent recurrent thickening and deepens the paranasal hollow anterior to the medial canthal attachment, which is important in obtaining a good result.

Fig. 34-45 This young girl was run over by a motorboat propeller. **A**, Her upper and lower eyelids were lacerated and partially avulsed, and the propeller passed through the anterior cranial base. The globe was preserved. **B** and **C**, Two axial CT views show the associated orbital wall injuries. **D**, The patient is shown postoperatively after reduction and fixation of the zygomatic fracture; cranial bone grafts to the orbital roof, medial wall, and floor; and meticulous repair of the eyelid injuries. The medial rectus muscle was mildly damaged. The patient may require an adjustment of the medial and lateral rectus muscle insertions. (Courtesy of S. Anthony Wolfe, MD.)

Correction of Secondary Lower Eyelid Laxity and Retraction

Lower eyelid retraction can be caused either by laxity—or retraction with an adequate amount of skin—or a skin deficiency. In both instances correction can be difficult, and on occasion it can require several stages.^{9,43-45}

With minimal laxity and adequate skin, a lateral canthopexy may be adequate. This can be performed through a coronal incision (if one is used for other reasons) or through an upper eyelid incision (lateral retinacular canthopexy). A more powerful canthopexy can be performed by developing a dermoorbicular pennant flap, bringing it through a burr hole in the lateral orbital rim, and sewing it to the temporal fascia (Fig. 34-46; see Fig. 34-10). When skin is deficient, a laterally based flap of upper lid skin or a full-thickness graft can be used.

Fig. 34-46 The steps in a lateral canthopexy. Tarsal strip techniques are generally not useful in children because of insufficient lid laxity. The dermoorbicular pennant procedure, however, can provide a very strong lateral canthopexy. **A**, The flap is extended laterally from its base on the upper and lower eyelids and deepithelialized. **B** and **C**, A 3 to 4 mm hole is drilled through the lateral orbital rim in the desired position of the canthus. The flap is passed through this hole and sutured to the periosteum of the lateral portion of the orbital rim.

If the soft tissue of the lateral canthal area is of poor quality (as might be the case in a patient with neurofibromatosis or blepharophimosis), a palmaris longus or short toe extensor tendon graft can be taken and split into a Y, with two limbs sutured to the tarsal plates. After 5 to 6 months, it can be used in a similar fashion to the dermoorbicular pennant.

Mild eyelid retraction with good canthal position and adequate skin can be treated successfully with a split palatal graft.

CONCLUSION

The management of malformations, neoplasms, and trauma of the eyelids in children differs little from that in adults, with the proviso that any condition preventing light and images from reaching the retina must be addressed immediately to prevent the development of amblyopia. Lid laxity and excess skin are rare in children; these are variables that could be used for correcting many defects.

Colobomas of the upper eyelid that result in a lack of corneal protection need to be corrected immediately to prevent corneal exposure and scarring. However, in congenital facial palsies such as Moebius syndrome, which involves lagophthalmos, this seems to be much better tolerated by children than adults.

The principles of eyelid reconstruction have been outlined: the inner lamella must be reconstructed with a structure that is both rigid and covered with mucosa. Only septal and upper lateral cartilage chondromucosal grafts and split palatal grafts fulfill this requirement. Outer lamella or skin can be provided from a number of sources. We find that the medium-thickness skin grafts from the upper inner arm or skin from the contralateral upper eyelid is best for the upper eyelid; the lower eyelid, which has no mobility requirements, can be covered with full-thickness skin grafts from the retroauricular or other regions. When possible, the levator should be attached in upper eyelid reconstructions.

Finally, close collaboration with a pediatric ophthalmologist is important in most cases.

KEY POINTS

- Congenital and acquired deformities of the eyelids in pediatric patients present a unique and complex treatment challenge for plastic surgeons.
- Corneal protection is paramount. Several days of treatment with corneal lubricants and a wet chamber is possible, but a cornea that remains exposed and shows signs of desiccation is a surgical emergency.
- The risk of amblyopia is a major consideration in pediatric patients with eyelid deformities. Conditions that either obstruct the visual axis (deprivation amblyopia) or distort the globe (anisometropic amblyopia) necessitate urgent care. Patients in whom amblyopia is suspected need to be referred to an ophthalmologist for evaluation.
- An interdisciplinary approach (plastic surgeon, ophthalmologist, and neurosurgeon) may be necessary for complex eyelid or craniofacial malformations.
- Eyelid reconstruction of any sizable defect must at a minimum provide an outer and inner lamellar skin cover, a mucosal structure to be in contact with the cornea, and structural support to mimic a tarsal plate (either septal, upper lateral, or ear cartilage or the inherent rigidity of a split palatal graft).
- The lower eyelid does not require mobility, but the upper eyelid does; therefore the lower lid may be used for upper lid reconstruction (Mustardé cross-lid switch flap), but the upper lid should not be used for the lower lid. (We agree with this as far as using the entire upper lid for the lower lid, but we do find it useful to use tarsoconjunctival flaps from the upper lid for marginal defects of the lower lid.)
- Tarsal strip techniques are generally not useful for lateral canthal tightening in children, because lid laxity is insufficient.
- An algorithm for the treatment of eyelid defects will provide a logical progression of treatment modalities, depending on the size of the defect.

Congenital and Acquired Deformities of the Nose

Fernando D. Burstein • Bruce S. Bauer

As the central and prominent feature of the face, the nose commands front billing, and even minor nasal abnormalities and discrepancies draw immediate attention. There has always been an inherent desire in people to look like their fellow humans and not appear peculiar or different.¹ The complex sequence of events that shapes the frontonasal structures and functional airway is vulnerable to atypical cellular processes and deformational forces that may cause minor abnormalities in nasal shape at one end of the spectrum, or near-total absence of nasal formation at the other end. After the normal nose has formed, its prominent position makes it subject to the forces of trauma, particularly in healthy, active children. Regardless of whether the deformities result from abnormal developmental processes or an errant bat during Little League, there is a need either to create a more normal appearance or restore the structure so that pediatric patients can interact comfortably and successfully with their peers. Although other chapters address nasal deformity resulting from cleft lip and palate (CL/P), the range of nasal clefts in atypical craniofacial clefts (see Chapter 26), and primary rhinoplasty for adolescents with indications and techniques (see Chapter 36), this chapter will review the diagnosis and treatment of some of the more common conditions that may affect the development and/or appearance of the nasal structures. These conditions include nasal hypoplasia, atypical nasal clefts, congenital nasal masses, vascular lesions, cutaneous lesions, and traumatic nasal deformities.

NOSE EMBRYOLOGY

During the fourth week of gestation, neural crest cells migrate to the developing face from the lower forebrain, the midbrain, and rhombomeres 1 and 2 of the upper hindbrain. These migratory neural crest cells are the predominant source of facial connective tissue, including cartilage, bone, and ligaments. Because neural crest cells migrate to the face as cohorts of cells from different portions of the brain, they carry with them different developmental programs. Mutations arising in the premigratory or early migratory neural crest cells may affect a specific clone of cells, which then carries that mutation to a predestined site in the face.²⁻⁶

At week 4, five identifiable primordia surround the stomodeum (Fig. 35-1). The single, unpaired frontonasal prominence lies in the midline just superior to the stomodeum.² By the end of the fourth week, even before the neural folds close, paired thickenings of ectoderm appear on the surface of the frontonasal prominence just superolateral to the stomodeum. These oval nasal placodes, located at the 1 o'clock and 11 o'clock positions, give rise to the future nose and nasal cavities. Development of the nasal placodes (and the lens placodes) requires the presence of the paired box gene *PAX6*. In the absence of *PAX6*, neither the nasal placodes nor the lens placode develops.² During the fifth week of gestation, mesenchyme in the margins of the nasal placodes proliferates to form horseshoe-shaped elevations—the nasomedial and nasolateral processes. The nasomedial processes are longer than the nasolateral processes.³ The tissue surrounding the placodes thickens and elevates so the nasal placodes appear recessed within depressions in the surrounding tissue, which are designated the *nasal pits*. The *nasal pits* are the primordia of the anterior nares (the future nostrils) and the nasal cavities.³

From the fifth week of gestation, the nasal pits gradually deepen toward the oral cavity, forming substantial depressions. By 6½ weeks' gestation, only a thin *oronasal membrane* separates the oral cavity from the nasal cavities. This oronasal membrane then breaks down so that the oral cavity can communicate with the nasal cavity through openings posterior to the primary palate.² These openings are designated the *nasal choanae*. Fusion of the two palatal shelves lengthens the nasal cavity and carries the communication posteriorly to the upper pharynx. The nasal septum grows down from the frontonasal prominence to the level of the palatal shelves when the shelves fuse to form the definitive secondary palate. The fusion of the primary palate with the secondary palate is marked by the incisive foramen.⁷

From the sixth to eighth weeks of gestation, the cheeks and corners of the mouth form by the merging of the maxillary and mandibular processes. The upper lip is completed in the latter part of this period.² Concomitantly, the expanding nasomedial processes merge with the superficial region of the maxillary processes on both sides along epithelial seams called the *nasal fins*.² *Mesenchyme* penetrates the nasal fins and forms continuity between the nasomedial and maxillary processes. The fusion of the two nasomedial processes displaces the frontonasal prominence posteriorly. Therefore the frontonasal prominence does not contribute significantly to the definitive upper lip, jaw, or nasal tip, despite the fact that it formed a prominent portion of the stomodeal border earlier. The fusion of the paired nasomedial processes forms the nasal tip, the crest of the nose, and a portion of the nasal septum.²

Facial and limb malformations are known to result from deficient or excess molecular signaling (such as Sonic Hedgehog, fibroblast growth factor, and retinoic acid signaling). Similar phenotypes, such as clefting, may result from either the deficiency of the appropriate midline tissue or the excess of other midline tissue that the appropriate processes cannot meet to fuse. In experimental animals, reduced retinoic acid signaling diminishes the expression of Sonic Hedgehog and fibroblast growth factor 2 in the mesenchyme, increases apoptosis locally, and decreases prolifera-

Fig. 35-1 Embryogenesis of the face from 4 to 10 weeks' gestation shows the contribution of the frontonasal process and the developing nasomedial and nasolateral processes to the formation of the nose, while the structure of the lip forms around the developing stomodeum and the nasal pit deepens.

Fig. 35-2 A, Newborn infant with a hypoplastic forebrain, nasal hypoplasia, and absence of the premaxilla, derived from the frontonasal process. Experimentally reduced retinoic acid signaling diminishes the expression of Sonic Hedgehog and fibroblast growth factor 2 in the mesenchyme, increases apoptosis locally, and decreases proliferation of tissue in the forebrain and frontonasal process. Animals with reduced retinoic acid signaling show a holoprosencephalic phenotype similar to what is seen in this neonate. B, Conversely, as shown in this infant with frontonasal dysplasia, excess Sonic Hedgehog stimulates frontonasal growth and widens the frontonasal process, resulting in cleft palate. More severe phenotypes include infants with frontonasal dysplasia or median facial cleft.

tion of tissue in the forebrain and frontonasal process. These animals show holoprosencephalic phenotypes with hypoplastic forebrains, fused eyes, and the absence of structures derived from the frontonasal process.^{2-4,7,8} Conversely, excess Sonic Hedgehog stimulates frontonasal growth and widens the frontonasal process by an average of 48%, resulting in cleft palate, and more severe phenotypes show ectopic midfacial structures with duplication of the nasal bones²⁻⁹ (Fig. 35-2).

FACIAL SKELETON AND NASAL STRUCTURES

The cartilage of the nasal capsule is the foundation of the upper part of the face.¹⁰ The bony elements of the facial skeleton appear around the nasal capsule and partly replace it. The lateral masses of the ethmoid form by endochondral ossification of the nasal capsule. The frontal processes of the maxillary bones, premaxillary bone, nasal bones, lacrimal bones, and palatine bones all form in membrane in close relationship with the roof and lateral walls of the cartilaginous nasal capsule.¹⁰ The vomer develops in membrane in relation to the perichondrium of the septal process. Eventually, nearly all of the nasal capsule becomes ossified or atrophied. All that remains of the nasal capsule cartilage in adults is the anterior part of the nasal septum and the alar cartilages that surround the nostrils.¹⁰

Specifically, the midline septal cartilage is continuous with the cartilaginous skull base. At birth, the skull base has three major ossification centers, and the septal cartilage has not yet ossified. The lateral masses of the ethmoid have ossified, forming the paramedian bones, but the cribriform plate is still cartilaginous or fibrous. Therefore at birth, the entire midline of the face

may be a lucent strip of cartilage situated between the paired lateral ossification centers. This lucent midline can simulate a midline cleft from the nares to the presphenoid bone.¹⁰ Because the appearance of the nasal septum varies with the patient's age, one must carefully interpret imaging "evidence" of midline defects and sinus tracts. In 14% of patients younger than 1 year of age, there is no midline ossification of the anterior fossa or septum.¹⁰⁻¹³

OVERVIEW OF CONGENITAL NASAL ANOMALIES

Losee et al¹³ presented a classification scheme for congenital nasal anomalies based on a review of 261 patients seen over a 22-year period at the craniofacial center at The Children's Hospital of Philadelphia. They separated anomalies into four types:

- Type I: Hypoplasia and atrophy
- Type II: Hyperplasia and duplications
- Type III: Clefts
- Type IV: Neoplasms and vascular anomalies

These types account for 62%, 1%, 16%, and 20% of cases, respectively. The high association of both type I and type III anomalies with craniofacial syndromes may somewhat skew the prevalence of these groups of anomalies in this chapter. Type I anomalies include paucity, atrophy, or underdevelopment of skin, subcutaneous tissue, muscle, cartilage, and bone in varying degrees. Although arhinia and unilateral nostril agenesis are quite rare, lesser forms of nasal hypoplasia are very common as part of many craniofacial syndromes. Type II anomalies involve an excess of tissue and include the spectrum of deformities from bifid septum and columella associated with dermoid cysts and sinuses, to the rare proboscis lateralis. Type III anomalies include Tessier nasal clefts¹⁴ (Tessier 0, 1, 2, and 3) and their cranial extensions (Tessier 11, 12, 13, and 14). These clefts usually result in hard and soft tissue deficiencies and are also frequently associated with other craniofacial syndromes. Type IV anomalies include congenital masses, such as the spectrum of dermoid neoplasms, glioma, encephalocele, vascular malformations, and benign and malignant neoplasms. Although we have taken a slightly different path with the basic sections of this chapter, it may be helpful to keep the Losee types¹³ in mind when one is considering the spectrum of congenital nasal lesions.

Congenital Absence of the Nose

From a review of the previous relatively brief discussion of the very complex processes that occur in the development of the nose, it appears that much rests on the effects of molecular signaling and tissue patterning in the face. Sonic Hedgehog may be the morphogenic organizer, whereas fibroblast growth factors may serve as the stimuli for mesenchymal outgrowth. Insufficiency of the frontonasal and nasomedial processes may result in hypoplasia or absence of the nose and intermaxillary segment (see Fig. 35-2, *A*). If there is decreased proliferation in the forebrain and frontonasal processes, the plumping of the nasomedial and nasolateral processes do not progress or progress incompletely. The ectodermal sculpting that should progress to create the nares, and the gradual breakdown to communicate with the pharynx, may either not progress at all or progress incompletely (Fig. 35-3). Lesser distortions of this process may result in isolated nasal deformities, with incomplete canalization of the nares and residual soft tissue and cartilage masses within the nasal airway. Not surprisingly, given the intimate relationship between the developing brain and central facial structures, the most severe forms of nasal hypoplasia may be associated with brain anomalies (often in the holoprosencephaly spectrum)^{15,16} (see Fig. 35-2, *B*).

Given the fact that newborn infants are obligate nose breathers, children born with either incomplete formation of the nose or total absence of the nose have the same emergent problem as children born with complete choanal atresia, and after immediate intubation, these infants need a tracheostomy. Subsequent reconstruction of an absent nose is complicated by hypoplasia of the supporting tissues (both nasal and maxillary, cartilaginous and bony), soft tissue deficiencies, and the desire to create a functional nasal airway and maintain its patency, if possible. These procedures may need to be staged over many years and are not typically completed until the affected child reaches skeletal maturity (Fig. 35-4). A combination of forehead flaps, nasolabial flaps, and local tissue advancements is necessary for soft tissue coverage.^{17,18} Cranial bone grafts, rib grafts, and conchal grafts can be used for skeletal reconstruction. Microsurgical tissue transfer may be essential in the most severe cases to provide enough tissue for internal lining and external covering.

Fig. 35-3 This infant has a rare combination of nostril agenesis and a complete bilateral cleft lip. The border of the nostril is evident on the left side, but the nasal pit failed to deepen and break through the buccopharyngeal membrane. Consequently, there is a solid mass of tissue in the airway to the level of the piriform margin, where the posterior airway is patent.

Fig. 35-4 **A**, This child was born with severe nasal hypoplasia, absence of the nasal airway on the right side, a hypoplastic nasal passage on the left side, mild hypotelorism, and a midline cleft of the lip. Additional anomalies were noted in the heart and gastrointestinal tract. She showed no CNS anomalies. During her first week of life, she underwent a tracheostomy. **B**, A three-dimensional CT scan showing frontonasal hypoplasia, medialization of the orbits, absence of a nasal passage on the right side, and presence of a nasal passage at the level of the piriform margin larger than what is seen at the skin level. **C**, After an initial failed attempt to reconstruct the external nose with expanded regional flaps when this patient was 5 years of age, formal reconstruction with expansion of the forehead was begun when she was 9 years of age.

Fig. 35-4, cont'd D, Two weeks before forehead flap reconstruction, regional flaps were elevated around the nostril pit on the left side, and bone was drilled out to open the airway to the point where the local surface flaps could be sutured to lining tissue behind the piriform aperture. E, Tissue expander in place and flaps healed around the reconstructed left nasal passage. F-H, Incisions were made at the borders of the planned external nasal reconstruction, and the border flaps were turned toward one another to provide lining tissue for the left nasal vault and coverage for the combined cranial bone and cartilage grafts used for support beneath the forehead flap. A pseudonostril was created on the right side. Results are seen at I, 14 years of age, and J and K, 19 years of age.

Nasal Hypoplasia

Nasal hypoplasia can present in a number of ways and with varying degrees of deformity. The severity of the deformity may be a function of how early in development the normal processes are interrupted and whether the tissues required to form the individual nasal parts are not developed, partially developed, or present but displaced. Nasal hypoplasia can be associated with dwarfism and other genetic conditions¹¹ (Fig. 35-5; see also Fig. 33-3). Trauma at an early age can also re-

sult in lack of nasal growth. The nasal dorsum may be very low because of a lack of growth of the nasal bones and septum.^{8,9} Less frequently, the tip cartilages themselves may be hypoplastic, with resultant aesthetic and functional sequelae. The severity of the condition may not become fully apparent until skeletal maturation.

A functional airway must be established early, and it is generally advisable to allow time for growth of the nasal structures. Whenever possible in the initial corrective efforts, structures should be placed as aesthetically as possible before the child reaches school age. Typically, bone grafts that are placed early will need to be augmented in later years. We have found that there was growth of these grafts, but the growth was not sufficient to obviate the need for later augmentation. Early grafts may still have the benefit of stretching the overlying skin envelope (see Fig. 35-5). Definitive reconstruction may be delayed until the child is close to skeletal maturity. Reconstruction through an external rhinoplasty approach can yield gratifying results. Autologous cartilage grafts from the septum, conchae, and rib serve as the framework for nasal reconstruction. Wide undermining of the nasal skin to the frontal bone superiorly and the maxilla laterally usually yields enough soft tissue to cover the framework.

Facial Clefts

Deranged development of the frontonasal process and/or failure of adjacent processes to merge successfully results in a coherent series of malformations.^{15,16} The insufficiencies of the previously described frontonasal and nasomedial processes result in some of the common manifestations of holoprosencephaly.^{8,9,11} Failure of the two nasomedial processes to merge in the midline produces the more rare, true midline CL/P with hypertelorism. These defects and the full spectrum of typical and atypical clefts have varied effects on the overall structure of the nose (Fig. 35-6; see Figs. 35-7 through 35-10). A discussion of the typical cleft lip nasal deformity and a review of the classification and features of atypical nasal clefts appear elsewhere in this book. Several different anatomic classifications for rare craniofacial clefts have been reported. In 1976 Tessier¹⁴ proposed a new system of classifying facial and craniofacial clefts based on the orbit as a reference structure. He recognized that there was both a soft tissue and a bony component to these clefts. His system attempts to offer common terminology for the description and treatment of these rare and complex clefts. As noted earlier and described in detail in Chapter 26, the Tessier nasal clefts include clefts 0, 1, 2, and 3, with their cranial extensions being Tessier clefts 11, 12, 13, and 14. Kawamoto¹⁹

Fig. 35-6 This infant was born with bilateral Tessier number 1 through 13 clefts and asymmetrical number 3 clefts without clefting of the lip, associated with a small encephalocele.

Fig. 35-7 A, This 5-year-old boy was born with a Tessier number 2 cleft on the left that was not associated with any bony anomaly. B-E, Outline of the nasal flaps, including both skin and cartilage, used for the cleft repair. F and G, Result 2½ years after the first surgery and 6 months after a revision procedure to modify a limited alar web.

reported that the incidence of these atypical clefts ranged from 1.43 to 4.85 per 100,000 births, making them far rarer than typical CL/P malformations. David et al²⁰ studied these rare clefts with CT and three-dimensional reconstructions, improving our comprehension of the anatomic anomalies and reconstructive challenges.

As with the design and planning of a typical cleft lip repair, the repair of nasal clefts in almost all patients requires rearrangement of the cartilaginous structures (with or without additional cartilage grafts and one or more types of Z-plasty lengthening procedures) to correct the vertical deficiencies inherent in all of these cases²¹ (Figs. 35-7 and 35-8; see also Fig. 35-6). For more complex clefts, repair often requires simultaneous correction of one or both eyelids and the lip (see Fig. 35-9), although other clefts may be confined entirely to the nose. Not surprisingly, most facial clefts need staged revisions as the child grows.^{22,23} Often the defect in these patients has a bony component that involves the maxilla and skull. Reconstructive planning in these complex cases requires bony and soft tissue reconstruction, which is staged as the patient develops. Complex reconstructive techniques, including soft tissue expansion, bone grafting, reconstruction of

Fig. 35-8 A, This child with Fraser syndrome, a rare autosomal recessive disorder, shows the features of cryptophthalmos and nasal anomalies, including a broad nose with a midline groove, depressed nasal bridge, and hypoplastic nares with Tessier number 3 clefts. B and C, Outline of Z-plasty to reposition parts of the disrupted alar margins carried out when the child was 4 years of age. D, Appearance 2 years after repair. E and F, Appearance at 12 years of age.

the lacrimal system, and on occasion craniosynostosis surgery, may be required. Often, if minor, these complex clefts can be resolved with local flaps. If major lateral nasal clefts are present, a combination of a forehead flap with tissue expansion and cartilaginous reconstruction in a staged fashion may be required (Fig. 35-9). Occasionally, composite grafts, usually from the concha, can be used to reconstruct the lateral ala with excellent color match and function. Clefts limited to the nose can vary in severity and include the upper and lower lateral cartilages, as well as bones in severe cases. Surgical techniques are individualized according to the severity of the cleft.^{1,24,25} Recognizing the deficiency of soft tissues and often bone in three dimensions can facilitate surgical planning and reconstruction (Fig. 35-10).

Fig. 35-9 **A**, This child illustrates the more “typical” type of Tessier clefts in combination with atypical clefts and hypoplasia resulting from amniotic band syndrome. **B**, Markings for surgery when the child was 13 months old, after tissue expansion, showing the initially proposed combination of advancement flaps, Z-plasties, and forehead flaps, in addition to planned repair of the lip and palate clefts. (Earlier surgery was delayed because of neurologic issues and delayed scalp healing.) **C**, Result at 1½ years of age after the outlined single surgery, along with conformer expansion of the reconstructed eye socket and placement of an ocular prosthesis. **D**, Ten years after repair, awaiting further reconstruction.

Fig. 35-10 **A**, Median facial cleft seen before correction. **B** and **C**, On dissection of the duplicated nasal structures and cranial base, a paired cartilaginous structure was dissected free, which was split in a manner that allowed the superior leaves to be turned upward and create separation of the cranial base; the inferior leaves were turned to create both the nasal floor and cartilaginous septum. The soft tissues were draped over these structures to provide vascular lining. **D**, Next, the lip and soft tissues of the nose and midface were repaired and the cranial vault reconstruction completed. **E**, At 1 year after the initial repair, there was still inadequate soft tissue in the columella, and both lip and midline nasal tissue were shifted to provide the additional tissue. **F-I**, At 1½ years after the initial repair, the added soft tissue of the columella was augmented both with a modified Tajima columellar lengthening, and combined costal and conchal cartilage grafts.

Nasal Masses

Nasal masses in the pediatric population have various causes, and proper diagnosis is essential to optimal treatment. The differential diagnosis includes nasal dermoids, gliomas, encephaloceles, and vascular lesions (hemangioma and vascular malformation). The embryologic development of the frontonasal region helps to explain how dermoids, gliomas, and encephaloceles represent a continuum in the disrupted process.^{11,26-30} Early in the developmental process, there is a potential space between the developing frontonasal bony structures and nasal capsule, which develop the nasal cartilages. This prenasal space represents an embryonic “fault line” from the foramen cecum to the skin surface (Fig. 35-11), as clearly shown in the classic paper by Sessions.³¹

Physical examination can usually but not always narrow the differential diagnosis. An MRI with contrast and often a complementary CT scan may be necessary to determine the extent of a lesion. MRI has the advantage of not irradiating the radiosensitive tissues of the eye and is therefore the preferred diagnostic method. The embryologic development of the previously discussed frontonasal region helps to explain the basis for dermoids, gliomas, and encephaloceles^{11,26-31} (Fig. 35-12; see also Fig. 35-11).

Nasal Dermoids

The presence of a frontonasal dermoid may be noted at birth or in early infancy as a midline pore, possibly with protruding hair and possibly with associated widening of the nasal dorsum¹¹ (Figs. 35-13 through 35-16). Nasal dermoids represent the most common congenital nasal mass. Some children may initially present with an infection in the cyst, with swelling and erythema anywhere from the glabella to the nasal tip (see Figs. 35-15 and 35-16). On rare occasions, a child may present with a brain abscess without previous recognition of the cyst or sinus opening from which the infection arose³²⁻³⁴ (see Fig. 35-14).

Fig. 35-11 The frontonasal structures develop with an embryonic “fault line” through the area of the prenasal space. The weak points are through the area of the foramen cecum and the fonticulus nasofrontalis, which lies at the frontonasal suture.

Fig. 35-12 Spectrum of nasal cysts and masses. Classification depends on location and what tissue remnants are left behind. A, Dermal sinus with intracranial extension. B, Dermal sinus tapering to fibrous tract that extends through the foramen cecum. C, Dermal cyst alone. D, Glioma. E, Encephalocele.

Fig. 35-13 A, This 2-year-old child had obvious swelling and a palpable cyst on the nasal dorsum with an overlying sinus opening. B, The tract was cannulated with a lacrimal probe at the time of excision. C and D, The cyst and sinus before final resection, and fully excised overlying the lacrimal probe.

Fig. 35-14 A, This 6-year-old boy was first seen with an intracranial abscess. On close inspection of his nose, a sinus opening was detected at the nasal tip.

Fig. 35-14, cont'd **B** and **C**, Coronal and axial views show the defect at the level of the foramen cecum. **D** and **E**, Anatomy of the cyst in both sagittal and three-dimensional views of the cup-shaped foramen cecum, widened by the presence of the intracranial portion of the dermoid cyst. **F**, The full length of the extracranial tract is shown. **G** and **H**, Intraoperative intracranial view of the dermoid cyst as resected from between the leaves of the falx cerebri and cup-shaped bony defect illustrated in **E**.

Fig. 35-15 **A**, This unusual dermal cyst and sinus extended not only intracranially but also intraparenchymally (into the frontal lobe). A small hair can be seen protruding from the sinus opening. **B**, MRI showing a cup-shaped defect in the crista galli. **C**, Intraparenchymal location of the cyst in another axial view. **D**, The “keyhole” frontal craniotomy is outlined, along with the planned osteotomy line for removing the frontonasal complex en bloc. **E** and **F**, Excellent views of the area between the falx cerebri, which provides access for resecting the portion of the dermoid within the frontal lobe. **G**, The frontonasal bony complex and frontal bone are replaced and fixed with absorbable plates.

Fig. 35-16 **A**, This infant had intermittent drainage from a sinus opening in the area of the glabella. Despite being given recommendations to proceed with resection, the family did not return for 4 years. **B**, Series of axial views through the area of the cyst, which had eroded the surrounding bone. The films were interpreted as showing long-term osteomyelitis. **C** and **D**, At the time of resection, the ragged edges of the bony defect were clearly visible.

Because the extent of soft tissue tracts may not be recognized beforehand, a CT scan or MRI is essential before surgery. The preference for one study over the other is mostly an individual one, and some lesions may require both studies to determine the continuity of the sinus tract through the foramen cecum and any presence of an intracranial component to the lesion.^{27,28} An MRI scan can provide valuable information regarding the soft tissue tracts associated with dermoids and help to differentiate normal anatomic variants of the anterior cranial fossa from sinus tracts penetrating intracranially (see Fig. 35-15, *B* and *C*). CT scans can provide the best picture of the bony anatomy of the nose and cranial base (see Figs. 35-14, *B* and *C*, and 35-16, *B*). CT scan data can even be translated into a life-sized anatomic replica of the patient's skull. These three-dimensional models can be a valuable planning and clinical adjunct if bony resection

and/or reconstruction is necessary. Lesions with intracranial extension either course beneath the nasal bones through a widened septum and then through the foramen cecum, or through a widened frontonasal suture and then the foramen cecum. In both cases, a bifid crista galli is usually noted on the CT scan, and an intracranial portion of the dermoid may lie between the leaves of the falx. Excision of these more complex lesions is facilitated by a cooperative effort between the plastic surgeon and neurosurgeon using a craniofacial approach.^{35,36}

The surgical approach to “simple” cysts or sinus and localized cyst alone varies, depending on the exact location on the nose or glabella. As previously described, the sinus opening at the base of the columella extends to the nasal spine only, and if associated with a cyst, the sinus is circumscribed for excision, and the remaining dissection of the cyst is accomplished through the labial sulcus. For the remaining sinuses and cysts from the nasal tip to the radix, one should choose the technique that allows the best view of the tract and its final point of attachment, with every effort to minimize the final scar (see Fig. 35-13). Some prefer excision of the sinus opening in combination with an open rhinoplasty approach³⁷; however, if the tract extends for any distance beneath the nasal bones, it may be very difficult to see. A poor field of vision during the first surgery may result in the problem recurring, so every effort should be made to remove the deep component during surgery. If the cyst or sinus is intimately attached to the skin, the tract may be difficult to obliterate if it is not excised directly, which may lead to recurrence. Sinuses and cysts of the glabellar area (fonticulus nasofrontalis origin) without intracranial extension may be approached through a curvilinear incision within the shadow of the lateral nose alone or in combination with excision of the sinus opening. This yields a barely visible scar and gives an excellent view of the area. A transnasal, endoscopically assisted approach has been reported for the resection of lesions that do not have an intracranial component.

For lesions with suspected or confirmed intracranial extension (see Figs. 35-14 and 35-15), excision of the sinus opening begins from the external approach combined with a frontal craniotomy, with delivery of the tract through to the fully exposed frontonasal area, following it through to its intracranial terminus.³⁸ For tracts that seem to terminate in a foramen in the bone, a biopsy will confirm the presence or absence of epidermal elements in the tract. If confirmed, a limited craniotomy is performed for access. For more complex lesions and those with confirmed intracranial extension, the previously described approach is combined with an en bloc removal of the frontonasal bone with direct visualization of the tract, crista galli, and falx through a keyhole osteotomy^{39,40} (see Fig. 35-15). Immediate reconstruction of the nasal and cranial defects is preferred. For patients who have had a significant amount of the bony and cartilaginous skeleton of the nose resected, the nasal dorsum should be reconstructed with a combination of cartilage and bone grafts. If the cartilaginous defect is small, a conchal graft may suffice, but if the defect is larger, a costal cartilage graft is preferred. Most defects resulting from a keyhole resection involve the frontal bone and anterior base of the skull. Cranial bone grafts are optimal for reconstruction and are usually obtained from the parietal bone. Preserving a large, anteriorly based pericranial flap allows its interposition between the dura and reconstructed anterior fossa, separating the nasal contents from the dura.

Donor defects are created if the skull is too thin to split. These defects are behind the hairline and can be repaired satisfactorily with allograft and demineralized bone matrix paste. Because these lesions typically occur in the infant or pediatric age group, nasal and frontal sinus development may be affected. Often further nasal reconstruction will be necessary in the teenage years. This is done through an external approach for optimal visibility using autologous cartilage grafts, which can often be obtained from the septum. Frontal sinus hypoplasia can occur after keyhole resection if the frontal sinus origins are disturbed, but this usually does not manifest until adolescence. The external manifestation is a visible depression occurring just above the nasofrontal juncture. This can be corrected with gratifying aesthetic results by using hydroxyapatite cement and a bicoronal approach.

Nasal Gliomas

Nasal gliomas represent heterotrophic neural tissue resulting from deficient regression of neurologic tissue in embryonic development.⁴¹ Gliomas in an extranasal location may still penetrate the bone in the frontonasal suture area and are often associated with both broadening of the nasal root and increased intercanthal distance (Figs. 35-17 and 35-18).

Continued extension through the widened foramen cecum and attachment to the dura in the area of the falx should be ruled out by MRI scan. An MRI scan can distinguish the interface between cartilage, bone, and brain in the region of the frontonasal area. Dural continuity can be ruled out by metrizamide cisternography if the MRI is not definitive.⁴² Gliomas presenting intranasally are usually noted first during physical examination in association with complaints of nasal airway obstruction or evidence of nasal bone distortion resulting from an expanding intranasal lesion¹¹ (Fig. 35-19).

Most often gliomas are confused with hemangiomas.^{41,42} After the diagnosis is made and the extent of the lesion is determined, the lesion can be excised. The surgical approach is again

tailored to allow viewing and excision of the entire lesion. Lesions with an intracranial communication may require a frontal craniotomy for complete excision. Extranasal lesions may require excision of the overlying skin with flap reconstruction when the skin is involved. Endoscopically assisted excision with a modified external rhinoplasty approach may be possible for lesions with a subcutaneous presentation and no intracranial involvement. Histologic examination reveals glial tissue, primarily astrocytes and fibrous tissue; occasionally neurons and ependymal cells are found.³⁷

Fig. 35-18 Extranasal glioma involving the overlying skin. **A**, This lesion masqueraded as a vascular lesion, but it was not compressible and did not fluctuate with breathing or a Valsalva maneuver. **B**, Defect in the nasal bone and underlying dorsal septum at the time of resection.

Fig. 35-19 Intranasal glioma. **A**, This 3-year-old child had a gradually enlarging mass in the left nasal cavity that caused splaying of the nasal bone. **B**, Anatomy of the intranasal glioma and its relationship to the overlying nasal bone.

Fig. 35-19, cont'd C-E, Coronal, axial, and midsagittal views of the glioma. F, Firm glial mass divided after resection.

Frontonasal Encephaloceles

Encephaloceles or meningoceles can also present as midline or paramedian nasal masses, usually at the nasofrontal area. A midline or paramedian cystic mass presents at birth and can reach enormous proportions (Fig. 35-20). Size fluctuation may be noted during crying or straining. In general much of the dural sac is filled with cerebrospinal fluid, but it may contain a herniated frontal lobe, along with amorphous glial tissue. Again, the most common path of herniation is through the open cranial base at the site of the previous foramen cecum and the widely patent frontonasal suture.^{15,16} Herniated tissue may extend well into the ethmoid air cells, in which an intranasal component is present. Encephaloceles may be associated with a widened intracanthal distance or true hypertelorism. MRI and MR angiography can give a detailed multiplanar image of the extent of the lesion, the vascular anatomy, and the presence of neural tissue in the herniated sac.²¹ Arteriography is often beneficial to determine the surgical approach and presence or absence of functional brain tissue. Significant defects of the nasofrontal area and anterior base of the skull may be present. A CT scan with three-dimensional reconstruction can give a complete picture of the extent and shape of the defect. A three-dimensional acrylic model, which may be sterilized for operative use, can provide valuable information for planning and executing the bony reconstruction. Treatment is best planned as a cooperative neurosurgical and plastic surgical effort. Histologically, the sac is lined by arachnoid tissue with possible heterotrophic glial tissue, which are accompanied by underlying bony and dural defects. Repair of both the dura and underlying bony defect, usually with cranial bone grafts, is recommended. Bone grafts can be cut

Fig. 35-20 **A**, Frontonasal encephalocele in a newborn infant. **B**, Midsagittal CT view shows a defect in the area of the previous fonticulus nasofrontalis. The continuity of the dura is also shown. **C**, The defect is shown on a three-dimensional CT scan. **D**, Intraoperative view of the encephalocele after it was fully exposed and before resection. **E**, A cranial bone graft was used to reconstruct both the anterior cranial base and nasal dorsum. **F**, Six months after repair. **G**, At 4 years of age, the child showed a trigonocephalic deformity with a prominent midfrontal ridge and antimongoloid slant to the orbits. This CT scan was obtained before craniofacial reconstruction with frontoorbital repositioning and frontal cranioplasty.

Fig. 35-20, cont'd H-J, One year after reconstruction.

and shaped with the three-dimensional representation. Frontal encephaloceles can often result in hypertelorism because of their extension into the ethmoid air cells. Such a residual deformity may require secondary correction, depending on the final aesthetic and functional outcome of the primary repair.

Nasal Hemangiomas

Nasal hemangiomas are one of the most common pediatric nasal masses. They may present as an external red or purple mass, but occasionally they can be entirely subcutaneous, presenting as a swollen nasal tip (see Figs. 35-21 through 35-25). They may have an intranasal component that can compromise nasal airway function. Although some spontaneous involution may eventually occur, nearly all hemangiomas of the nose require treatment to minimize long-term sequelae.⁴³ Physical examination is often sufficient to differentiate hemangiomas from arteriovenous malformations. These malformations are usually present at birth, may have a thrill when auscultated, and are high flow. Purely venous malformations are typically darker than hemangiomas and can be compressed. If a question persists regarding the exact nature of a lesion, an MR angiographic scan can resolve it in almost all cases. Strategic planning for approaching nasal hemangiomas should include minimizing external skin involvement, preserving function, and minimizing long-term distortion of the cartilaginous nasal skeleton.

Several approaches can be used to treat nasal hemangiomas successfully, including serial excisions, steroid injections, external laser treatment, intralesional laser treatments, and resection through an external rhinoplasty approach.⁴³⁻⁴⁶ We use a combination of these therapeutic options based on each patient's individual needs (Figs. 35-21 through 35-23). If a lesion is entirely subcutaneous with normal skin, significant shrinkage can be achieved through the use of intralesional potassium-titanyl-phosphate (KTP) or YAG lasers. This treatment is carried out every 4 weeks for a total of 3 to 6 treatments. A small amount (0.5 ml) of triamcinolone (Kenalog) 5% is injected into the deepest part of the lesion during each treatment. This small amount has not been found to cause subcutaneous thinning, and it helps to decrease proliferation of the hemangioma and to decrease scar tissue while the hemangioma becomes more fibrotic,^{43,46} which significantly

Fig. 35-21 A, This infant had a nasal hemangioma with an internal component causing partial airway obstruction. B, Appearance after serial treatments with a KTP laser, a Candela laser, and steroid injections.

Fig. 35-22 A, This infant had a nasal tip hemangioma with external and internal components. B, Appearance after sequential treatments with a KTP laser, a Candela laser, and steroid injections, and a subsequent external rhinoplasty approach. The residual hemangioma has been debulked and the nasal tip has been reconstructed.

Fig. 35-23 A, Large nasal dorsal hemangioma interfering with the right medial visual field. B, After initial treatment with KTP laser, Candela laser, and steroid injections to decrease the size of the lesion, the residual lesion was treated surgically with debulking and local flap reconstruction.

decreases the vascularity and size of the lesion. If any excess bulk remains 6 to 9 months after the final laser treatment, and there has been no gross regrowth of the hemangioma, an external rhinoplasty approach can be used to remove any residual mass effect.⁴³ A gull-wing incision that does not violate the nasal tip subunit allows excellent exposure to debulk the residual fibrofatty tissue and address the associated cartilaginous deformity. It also allows limited skin reduction, again without violating the subunits.

Often the medial crura of the lower lateral cartilages are splayed in a bifid appearance by the pressure of the hemangioma (Fig. 35-24). This can be reconstructed during an external rhinoplasty by simply suturing from the footplates to the domes, thus reversing the pressure changes

Fig. 35-24 A and B, This child, at 2 years 4 months of age, who had previously received steroid injections and laser treatment for hemangioma of the nasal tip, shows the typical Cyrano nasal tip deformity that follows a bulky hemangioma confined to the nasal tip. Excess fibrofatty and vascular tissue remain, causing the domes of the alar cartilages to splay apart. C, The initial resection was carried out through a gull-wing incision. The upper border of the resection line was estimated but was refined after the fibrofatty vascular mass was resected and the skin redraped. D, Result 1½ years postoperatively with residual vascular changes in the skin. E, Patient at 6 years of age, 4 years after resection.

Fig. 35-25 **A**, This infant had an extensive facial hemangioma with numerous ulcerations and significant deformation of the underlying alar cartilages. **B**, At 4 years of age, she underwent extensive debulking, partial skin resection, and repositioning of the distorted alar cartilages. **C**, Patient 3 months after a second debulking procedure and 2 years after the excision shown in **B**. **D** and **E**, Although the residual lesion involuted, the scars matured further, and the nose was allowed to grow. The child is shown at 7 and 16 years of age after the initial resection. **F** and **G**, The patient is shown 8 months after revision of the alar margin, with the addition of a small conchal cartilage graft.

of the hemangioma. If the hemangioma has significant skin involvement, or if the nasal tip skin has ulcerated during the most active proliferative stage, leaving permanent tip scarring, an external skin excision is necessary and may be preferable (Fig. 35-25). Often significant shrinkage of the lesion, as well as salvage of affected skin, can be achieved through a combination of external Candela laser treatment and internal KTP laser treatment. These treatments can be combined with local steroid injection to halt growth, minimize cutaneous involvement, and greatly facilitate the process of serial excision. After maximal shrinkage of the lesion has been achieved, an external excision with a serial approach is advocated. Wide undermining of the normal skin can be achieved, and this skin can be used to replace the involved hemangioma skin over a period of years. Serial excisions are combined with reapproximation of the medial crura, as previously described. In addition, reconstruction may require conchal cartilage grafts when cartilage deficiency is also present to give the best overall aesthetic result (see Fig. 35-25). On occasion, tissue loss can be significant enough to require reconstruction more typical for acquired deformities such as columellar loss and tip loss.

Cutaneous Lesions: Nonvascular

The range of congenital and acquired cutaneous lesions in the pediatric population is covered in Chapter 8. The smaller acquired lesions (0.5 cm or less) present the same issues and concerns as do acquired lesions in the adult population; however, congenital nevi, both melanocytic and sebaceous, may create particular concerns both in their extent and distribution⁴⁷⁻⁵⁰ (Figs. 35-26 through 35-29). Unlike reconstruction of acquired malignant lesions in adults, reconstruction of congenital nevi is typically confined to reconstructing the skin even for extensive lesions, because the underlying supporting cartilage and lining tissues are either uninvolved entirely, or the underlying supporting cartilage may be left intact, balancing concerns about potential functional disturbance and the likely low risk of later malignant degeneration.

Congenital Melanocytic Nevus

Congenital nevi of the nose are uncommon and may be confined to the nose alone or as part of a more extensive nevus of the periorbital region, hemiface, or bilateral face. Although the risk of malignant transformation of giant congenital nevi is well established, the risk of malignant transformation of congenital facial nevi appears to be less common; however, the psychological impact on a child and the child's family from a pigmented facial nevus can be profound. Additionally, some nasal nevi can produce a variety of functional problems from significant thickening of the subcutaneous tissues creating a bulk and weight that may compress the ala and secondarily narrow the nostril. For these reasons we advocate excision and reconstruction of these nevi.⁴⁹⁻⁵¹ Although some surgeons elect to delay the treatment of these very visible lesions until later ages, when nasal growth is more complete and some procedures may be easier, treatment delays may have a significant long-term impact on a child trying to deal with constant peer ridicule.

Treatment of Cutaneous Lesions

Staged Excision (With or Without Adjacent Tissue Expansion)

Although one must always design an excision and reconstruction with the aesthetic nasal subunits in mind, and give consideration to recruiting distant forehead tissue to provide coverage, excision of some of the nasal tip subunit, alar margin, and middle dorsum may be treated quite effectively using staged, serial excision, with or without local nasal tissue expansion (see Figs. 35-26 and 35-27). As long as underlying cartilage is left intact, even a limited reduction in nostril size (following the alar margin excisions) may yield excellent long-term outcomes, with only minor scar revisions of balancing procedures necessary near the completion of nasal growth.

Fig. 35-26 A congenital nevus involving the greater part of the alar subunit of the nose in this 11-year-old girl. Although this lesion is typically considered large enough to require a forehead flap or composite graft reconstruction, a staged excision and adjacent flap movement were performed. **A-C**, Three views of the area of involvement, which can be seen extending across the nostril margin but not intranasally. The resection and movement of flaps were done without resection of the cartilage. **D**, Results 2 months after first-stage resection. **E** and **F**, One and a half years after the first excision and 2 months after the second excision, the basal view shows the intermediate thickening of the soft tissues along the nostril margin. **G** and **H**, One year after the final thinning of the soft tissue along the nostril margin; the patient is 16 years of age.

Fig. 35-27 A, This 5-year-old girl had a bulky congenital pigmented nevus of the nasal tip and dorsum. Although excision and reconstruction with a forehead flap was an option, the lesion was excised with expansion of adjacent normal skin. B, Close-up view of the nevus before two 3 cc custom expanders were placed through an incision within the nevus that also allowed a conservative partial resection of the nevus. C, Appearance of the expanders just before resection of the remaining nevus. D, Patient 8 months after resection. E, Same patient at 10 years of age.

Fig. 35-28 Early stages of reconstruction in a child with a congenital giant pigmented nevus of the face. **A**, Patient at 6 months of age. **B**, After successful expansion that began at 1 year of age; with expanders in both the forehead and neck, the forehead flap was oriented so that the donor scar lies along the brow and continues out into the zygomatic temporal region. **C**, Appearance a few days after resection of the nasal nevus and expanded flap reconstruction. **D**, Six months after the procedure shown in **B**, an expander was placed in the child's cheek. After an additional 3 months of expansion, the remaining nevus of the cheek was resected, and the forehead flap was lifted from the nose, thinned, and replaced. Patient is shown 10 days postoperatively. **E-G**, At 10 years of age, she is still undergoing excision of remaining nevus in the eyelid and refining of the soft tissues of the nose and cheek. Final reconstruction is expected when the patient is a teenager.

Fig. 35-29 This infant was born with extensive sebaceous nevi, without associated central nervous system involvement. **A**, Larger lesions covered large segments of her scalp, and she had multiple linear lesions in the central and lateral portions of the face. This type of lesion is approached using a combination of tissue expansion and staged excisions of some of the narrower linear lesions. These excisions may be timed to allow partial excision at the time of expander placement and repeat excisions later at the time of more extensive excision and flap reconstruction. **B** and **C**, The first set of expanders at the completion of expansion. **D**, Patient's appearance 5 years after the start of staged excision and reconstruction, with the greater part of the nevus on the nose, forehead, and scalp excised but residual lesions in the nasolabial region, lip, and lateral eyebrow just before further excision.

Excision With Full-Thickness Skin Graft Coverage

Although nevus excision only involves the excision of skin and subcutaneous fat to the perichondrial or fascial level, full-thickness skin grafts typically do not provide an excellent long-term outcome. However, they may be beneficial for removing deeply pigmented, very visible lesions in children younger than some surgeons may be comfortable with. Although full-thickness skin graft coverage of the nose in combination with a single, large, expanded, full-thickness skin graft to the periorbital area has been used effectively in the past to provide excellent long-term results,⁵¹ we now prefer early coverage with an expanded forehead flap.

Expanded and Nonexpanded Forehead Flaps

Although there are differences of opinion regarding the benefits of expanding the forehead before using a forehead flap for nasal reconstruction, our extensive experience in treating large and giant congenital pigmented nevi of the face has showed unique benefits of the expanded forehead flap (see Fig. 35-28). When advancing the expanded central forehead laterally to excise nevi of the lateral forehead and temporal region, there is a relative “redundancy” of skin in the glabella and the ipsilateral side of the nevus excision. This tissue can be used based on the same supratrochlear vascular pedicle as a standard forehead flap, as a small flap to cover the nasal dorsum alone, or for total nasal coverage, with the added benefit that the donor scar will lie along the brow, rather than centrally in the forehead (see Fig. 35-28, *C* and *D*). Our experience with expanded forehead flaps in the early stages of treating large and giant nevi is still limited (in the 18- to 24-month age range), but our results clearly support its role as a powerful reconstructive option.

Linear Sebaceous Nevi

Linear sebaceous nevi may present in isolation as a lesion or a series of striped lesions on the nose, or as part of a larger more extensive facial sebaceous nevus associated with sebaceous nevus syndrome.⁵² Although some physicians have elected to treat linear sebaceous nevi with lasers alone, any remaining portions of a lesion require an extended series of treatments, and still may be visible enough to create an unsightly deformity. The skin between stripes of lesion is normal, and serial linear excisions can preserve this normal tissue and allow excellent long-term outcomes. With an extensive facial nevus, staged linear excisions of the nasal lesion may be performed during the same surgery by either placing tissue expanders, or removing them and undertaking an extensive excision and flap reconstruction (see Fig. 35-29). Because the latter procedures are typically carried out with 11 to 12 weeks of expansion, with a 4- to 6-month interval between each group of procedures, this allows multiple opportunities to serially excise nasal lesions.⁵²

ACQUIRED NASAL DEFORMITIES

Acquired nasal deformities are most commonly caused by trauma. Traumatic deformities can be divided into those with an open skin component and those of a closed nature. When either open or closed nasal injuries occur, they can result in permanent nasal deformities. If the injury occurs at a young age, these deformities may not become apparent until the child has grown, at which point they may present with a saddlenose deformity or even complete nasal hypoplasia.

Closed nasal trauma injuries are common, are associated with sports or occasionally fisticuffs, and may involve injury to both the cartilaginous and bony components of the nose (Fig. 35-30). The initial evaluation should include a thorough history to reconstruct the mechanism of injury and approximate the force of impact. Standard radiographs may not reveal the extent of injuries in a developing nose, because there is a tendency for the nasal bones to undergo greenstick fracturing rather than shatter. Plain radiographs are not a substitute for a thorough examination. Computerized tomography of the maxilla and nose in both the axial and coronal planes can provide useful clinical information. An intranasal examination is essential to determine whether a septal hematoma is present, which can lead to late pressure necrosis of the septum. A hematoma often presents as a unilateral purple swelling that can completely obstruct the nares. Patients with a septal hematoma often have pain that is disproportionate to the visible extent of their external nasal injury. Treating a closed nasal fracture consists of closed reduction and external splinting. If a septal hematoma is present, it should be drained, and any loose fragments of septum should be debrided.^{51,52} Plain gut is used in a continuous mattress stitch to approximate the septal mucoperichondrial flaps and prevent recurrence of hematoma (Fig. 35-31). An external thermoplastic splint is applied, and no intranasal packing is used. If a septal hematoma is present, a short course

Fig. 35-30 **A**, This 8-year-old girl had a bony and cartilaginous deformity of the nose that occurred when she fell off a horse. **B**, Same patient after closed nasal reduction.

Fig. 35-31 “Weave” technique for avoiding recurrent septal hematoma after evacuation.

of oral antibiotics is prescribed. After 1 week the splint is removed. Contact sports are not allowed for 4 weeks. Open surgery for acute treatment of a closed nasal fracture is not indicated, because the skin and periosteal attachments holding the comminuted nasal bones can be disrupted, making stabilization challenging. Sequelae of untreated nasal fractures with or without septal hematomas include airway obstruction, aesthetic deformity, and saddlenose deformity. Even if optimal treatment is administered, there may be a residual deformity that may become more apparent as facial growth progresses. Parents should be made aware of this possibility during the initial discussion of the injury and required treatment.⁵¹

Open injuries often occur as a result of motor vehicle accidents, falls, animal bites, and sports injuries. Isolated nasal trauma requires thorough intranasal and extranasal examinations. Plain radiographs and CT both can provide valuable information. As with closed nasal trauma,

it is imperative to determine whether there is a septal hematoma with open trauma. Open nasal fractures require reduction, inspection for septal hematomas, and prompt repair of the skin lacerations. CT scanning is recommended to rule out underlying maxillary injuries. If maxillary fractures are also present (and are more significant than nondisplaced greenstick fractures), they are treated with open reduction and resorbable fixation followed by closed reduction of the nasal bone fractures once the skin has been repaired. Wide undermining of the nasal skin should be avoided, because this further destabilizes bony fragments. Only obviously devitalized skin should be debrided, because even macerated traumatized skin is often viable. External splinting is used, and occasionally resorbable nasal packing is used for very unstable fractures. Antibiotics and analgesics are continued for 5 to 7 days. A conservative approach is recommended for the initial treatment of most open nasal fractures, followed by at least 12 months of observation. Approximately 40% of children who have significant nasal fractures exhibit a residual external or intranasal deformity when they reach skeletal maturity. Obstructive symptoms infrequently warrant intervention before skeletal maturity. A conservative approach is also recommended in these patients, with septal scoring and splinting, and turbinate reduction to improve the nasal airway if intervention is necessary before adolescence.⁵¹⁻⁵³ If there is a symptomatic residual deformity at skeletal maturity, it requires an open rhinoplasty approach, often with cartilaginous reconstruction, septal reconstruction, and fracture reposition of the nasal bones. Autologous cartilage is advocated if augmentation is required, especially for the nasal dorsum. Septal cartilage can be useful for small defects, but costal cartilage seems to be more effective for optimal long-term results with larger dorsal defects.

Animal bites are most commonly from canines. Young children are particularly vulnerable, because they are at face height to many dogs. Teenagers may tease or roughhouse with dogs, putting their noses at risk of bite injury. Generally, the initial puncture by a dog's teeth is followed by the victim pulling back, which often results in partial or complete tissue avulsion (Fig. 35-32).

Initial treatment should include debridement, updating tetanus prophylaxis, and oral and topical antibiotics. The first steps of treatment are inspection of wounds with removal of all definitively devitalized tissue and prevention of secondary infection. Given the excellent blood supply in the area, initial debridement should be conservative. After the tissues have demarcated their viability, the residual defect can be evaluated. If there is no significant tissue loss, scar revision may be considered 9 to 12 months after the initial injury, allowing time for scar maturation. If a true tissue avulsion is present, plans for a staged reconstruction should be discussed with the patient and the family. Depending on the defect, local rotation flaps, forehead flaps, or composite grafts may be necessary for repair.⁵⁴ Alar defects can be treated with local rotation flaps combined with conchal grafts or composite grafts for alar airway support. Larger defects of the skin and cartilage may require a forehead flap or nasolabial flaps, depending on the extent of tissue loss.⁵⁴ Tissue expansion may be valuable for obtaining sufficient soft tissue for reconstruction. If adequate soft tissue coverage is available, the underlying nasal framework can be reconstructed at the same time. Significant defects involving the tip, dorsum, and lateral nasal sidewall cartilage are best treated using rib cartilage to construct a framework for supporting the overlying soft tissue flaps. Once the initial framework and soft tissue reconstruction have been accomplished and healed, several refining procedures can be considered. These include scar reduction and debulking procedures, aesthetic tip-plasty, adding conchal cartilage grafts to minor defects, laser treatment of scars, and other modifications. Defects of the columella may require adjacent flaps, composite auricular grafts, or combinations of these procedures (Figs. 35-33 through 35-35). The patient,

the patient's family, and the treating plastic surgeon must all understand that reconstruction for extensive nasal defects will take multiple stages over a period of years. Significant improvement can be expected, but there will be residual donor- and recipient-site scars, and these will be permanent. The animal involved in a bite trauma must be checked for rabies and reported to animal control authorities. Because lawsuits often result from dog bites, careful documentation is essential, along with a conservative estimate of the final aesthetic and functional outcome. It is impossible for the surgeon to estimate the total number of procedures and final outcome after the initial intervention, although many insurers and attorneys demand this information.

Fig. 35-32 A, This teenager sustained a nasal avulsion injury after she was bitten by a dog. Note the loss of the lower lateral cartilage and caudal upper lateral cartilage with extensive skin loss. B, Technique for harvesting and applying conchal graft for nasal reconstruction. Note that a graft can also be harvested with overlying skin as a composite graft. C, Same patient after staged reconstruction using conchal grafts for cartilaginous nasal vault reconstruction and a left nasolabial flap for external and internal soft tissue reconstruction.

Fig. 35-33 A and B, This 4-year-old boy was seen for reconstruction of columellar and tip defects resulting from partial necrosis of the columella caused by the pressure of the nasal cannulas that were used while he was in the neonatal intensive care. C, The patient returned at 16 years of age after undergoing three operations, including an attempted columellar advancement according to the method of Cronin, two small composite grafts, and a scar revision. These procedures left him with considerable scarring and, according to the patient and his family, a more noticeable deformity. D, Lateral view before further reconstruction shows shortening of the columella, blunting of the nasal tip, and notching of the tip. E, Patient at 17 years of age after reconstruction using an open rhinoplasty approach. After osteotomy and infracture of the nasal bones, septoplasty and septal cartilage graft to the columella, and flap reconstruction using portions of the previous composite grafts for additional tip support, the shape of the columella and the nasal tip was restored. F, Lateral view 1 week after surgery shows improved tip projection and smoother contour of the columella. G and H, Two months after reconstruction. This patient was seen on one other occasion to discuss minor scar revision, but he elected to postpone this.

Fig. 35-34 This baby girl presented with a hemangioma that was rapidly destructive despite medical management. At presentation, she already had necrosis of her columella. **A**, At 13 months of age, a point involution was beginning. She was also diagnosed and underwent surgery at 2 years of age for moyamoya disease, an intracranial vascular malformation. **B** and **C**, At 2 years 9 months, her first surgery involved developing a flap based on the center of the enlarged upper lip, as a vascularized flap turned 180 degrees and inset into the tissue along the border of the central nose. This provided the needed tissue for the subsequent reconstruction of the columella. During the same surgery, the lateral nose and medial canthus and brow tissue were reduced. **D**, Seven months after the first surgery. **E**, Nine months after the first surgery and 1 month after the second surgery, further shaping of the nasal and lip soft tissues was performed. **F**, At 4 years, 6 months of age after the second surgery. **G-I**, At 9 years of age, which was 7 months after further reconstruction of the columella with a flap and conchal cartilage graft. She will be a candidate for additional scar revisions and strut graft in the future.

Fig. 35-35 Forehead flap reconstruction of an extensive defect that occurred after tissue destruction resulting from a hemangioma. **A and B**, This 14-year-old girl is shown after destruction of the soft tissues and cartilaginous support of the nasal tip and columella subsequent to an involuting hemangioma. The skin over the entire nose is scarred and atrophic. The columella and right rim had been repaired by means of local tissue rearrangement when she was a young child. **C**, The skin of the nasal units is marked for excision. **D-H**, The angle of the septal cartilage and the entire alar cartilage complex are absent. Templates were made to guide the exact replacement of the missing nasal skin and absent septal angle, tip cartilages, and alar support grafts. A triangle of septal cartilage was fixed to the residual septum with lateral spreader grafts to re-create the septal angle. Septal cartilage strips were fixed to the distal septum and hinged laterally to re-create the medial, middle, and lateral crura to restore support and contour to the distal nose.

Fig. 35-35, cont'd I and J, The nose was resurfaced with a full-thickness forehead flap. K, At 3 weeks, the forehead flap is healed to the recipient site. The forehead donor site, which could not be closed under the hairline, was allowed to heal by secondary intention. L-N, Three weeks after transfer, the forehead skin was re-elevated with up to 3 mm of subcutaneous fat. In this case it was maintained as a bipedicle flap hanging from its origin at the brow and from the distal columella inset. In most instances, the flap is completely elevated and temporarily positioned to the side of the face. The underlying excess of subcutaneous fat and frontalis is exposed. This is excised with a scalpel to re-create the subtle three-dimensional contours of the nasal surface. The flap is resutured to the recipient site with quilting and peripheral sutures. O, The flap was divided 3 weeks later, and its proximal aspect was returned to the forehead as a small inverted V at the brow. The forehead scar was subsequently revised. P-R, Postoperative result at 19 years of age. The excess fullness of the left alar base could be improved by minor revision. (Courtesy of Frederick J. Menick, MD.)

KEY POINTS

- The definitive nasal structures, both external and internal, develop during the fourth to eighth weeks of gestation concomitantly with the developing primary and secondary palate.
- Facial and limb malformations result from deficiency or excess of molecular signaling (such as Sonic Hedgehog, fibroblast growth factor, and retinoic acid signaling). Similar phenotypes, such as clefting, may result from either deficiency of the appropriate midline tissue or excess of other midline tissue so that the appropriate processes cannot meet to fuse in the midline.
- Because the appearance of the nasal septum varies in radiologic examination depending on the patient's age, one must interpret imaging evidence of midline defects and sinus tracts carefully. In fact, 14% of patients younger than 1 year of age have no midline ossification of the anterior fossa or septum.
- One can best understand the spectrum of congenital frontonasal masses (dermoid cysts and sinuses, gliomas, and encephaloceles) with a clear understanding of the embryology of frontonasal development and the paths of potential embryonic "faults" through the foramen cecum and frontonasal suture.
- The choice of radiologic technique to evaluate frontonasal cysts and sinuses varies partly on surgeon preference. Some surgeons think that the bone anatomy and area of the crista galli are better delineated with a CT scan, whereas others think that the sinus tract is better delineated with an MRI. Complex cases with intracranial extension may best be studied with the use of both.
- Dermal cysts and sinuses with obvious intracranial extension require a craniofacial approach typically through a keyhole frontal osteotomy with initial resection of the intracranial dermoid. For patients with indefinite extension, the tract is followed to its tapered stalk, and a biopsy specimen is taken to determine whether dermal elements exist. If they are present, the intracranial portion is addressed.
- For lesions with an intracranial component, a follow-up MRI is recommended yearly for 3 years to rule out recurrent growth of any dermal remnants that were missed during the initial surgery.
- If a portion of the cartilaginous septum is removed surgically when following the sinus tract, it should be repaired during the same procedure to prevent a saddlenose deformity. If the defect is small, conchal grafts can suffice; if the defect is large, a costal graft may be required.

- If there is a large defect in the frontal bone, the occipital bone can be switched to the frontal position to give a smooth contour to the forehead. The frontal bone defect is repaired with allograft and placed in the occipital position.
- Nasal hemangiomas can be confused with venous malformations or arteriovenous malformations. If physical examination does not clarify the diagnosis, MRA with venous phase views can be helpful.
- If a patient has a history of nosebleeds without ulceration of the external component, a significant intranasal component may be present. An MRA of the nose and face can reveal the internal extent of the lesion.
- When nasal hemangiomas are treated with laser therapy, more treatments with less intensity decrease ulcerations and burns. Power settings should be increased incrementally over several treatments until the minimal effective power settings are determined.
- The Cyrano nasal tip deformity is a common sequela of hemangiomas of the nasal tip, with the involuting lesion leaving excess fibrofatty tissue with splayed alar cartilage domes.
- Costal grafts are notorious for warping, but steps can be taken to prevent this. All of the perichondrium is removed, and a 0.4 mm K-wire is inserted and cut just below the surface of the cartilage. Alternatively, the rib cartilage can be cut longitudinally into thin layers that can be “bruised” with a cartilage crusher. These cartilage sheets can be stacked and sutured together to achieve the desired dorsum height.
- Standard radiographs do not always accurately reveal nasal fractures in pediatric patients, because bones can undergo greenstick fracture rather than an outright fracture. In addition, the cartilaginous septum cannot be seen on plain radiographs. Accurate initial clinical assessment for significant bony and cartilaginous deviation and septal hematoma is crucial. If swelling prevents satisfactory assessment, the surgeon should ask the patient to return in 5 days with an old anteroposterior photograph to use for comparison.
- The septum can be splinted with sterile radiographic film cut to fit and sutured with the septum in the middle. This is removed after 7 days.
- If secondary surgical correction is necessary after initial closed reduction in adolescents, the surgeon should allow 9 to 12 months for complete healing before rhinoplasty. This interval can reveal areas of dorsal cartilage loss or deviation that may not be apparent initially.

Primary Rhinoplasty in Adolescents: Indications and Techniques

Daniel R. Butz • Jeremy P. Warner

Adolescence is a critical time period for psychological and physical development. Nasal deformities can be a key source of distress, and many teenagers seek to undergo elective rhinoplasty.¹⁻³ Rhinoplasty is the most common elective cosmetic surgery performed in the adolescent population.⁴ Patients may present for aesthetic deformities, functional nasal airway obstruction, or both. Some people think that adolescents lack the intellectual maturity and insight to make decisions that will change their appearance forever.⁵ However, rhinoplasty has been found to be safe and effective and provides satisfactory patient outcomes.^{1,6}

INDICATIONS

In adolescent patients, surgeons must assess psychological maturity, desires, and expectations. This assessment should be coupled with the support and expectations of the parents. Patients should be near physical maturity to prevent disruption of nasal growth. Akgüner et al⁷ reported that females have adult nasal proportions and growth by 13 years of age and males by 15 years of age. In general, females should be 1 year postmenarche with stable growth.

Although the focus of rhinoplasty is generally on the aesthetic deformities and outcomes, patients with functional deformities often have significant airway obstruction. Those who present with specific and realistic requests are more likely to be satisfied with the postoperative outcome.⁸ Ideal patients have identifiable deformities, such as a dorsal hump, nasal deviation, a hooked tip, a pollybeak deformity, or a large nose. Surgeons should proceed cautiously with a patient who

brings in magazine clippings and requests to have a specific celebrity's nose.⁹ Similarly, those who present with minimal deformity but describe significant social, occupational, or functional disturbances should be questioned further and a psychological referral made when necessary. Body dysmorphic disorder typically develops during late adolescence.¹⁰ Finally, patients with an ethnic nose who seek a "white" nose should be counseled about realistic expectations.^{2,9}

PREOPERATIVE ASSESSMENT AND CONSULTATION

A preoperative assessment should include a thorough history and physical examination. A history of psychiatric illness is a relative contraindication to surgery, and unrealistic expectations are an absolute contraindication to surgery. Both the patient and parents must have similar expectations.

A thorough physical examination of the internal and external nose is performed.^{11,12} The skin type, thickness, and presence of any lesions or scars are noted. The dorsal aesthetic lines from the medial brows to the tip of the nose are inspected, and the overall shape and width of the tip are evaluated. From the lateral view, the radix position and dorsal profile are examined in the upper and middle thirds. Dorsal deformities, such as a dorsal hump, or saddlenose deformity, are noted. The tip length, projection, and rotation are analyzed. The infratip appearance, columellar position, nasolabial angle volume, and alar-nostril shape and size are also considered. A thorough functional examination will include an evaluation of the septum, inferior turbinates, internal nasal valves, and external nasal valves.

Surgeons must take photographs at the initial consultation and review them with the patient. This allows patients to express their concerns in detail and to clarify the surgical goals.¹³ Standard photographs include frontal, oblique, lateral, and worm's-eye views of the face. Using modern computer software, surgeons can show patients how their nose might look after the surgery is complete.^{14,15} Although computer software can be a powerful tool for communication between a surgeon and patient, realistic expectations and limitations must be thoroughly discussed. I (J.P.W.) use three-dimensional imaging in my office to work toward a common goal with the patient. I stress that healing can cause the actual final outcome to vary from the final outcome shown on the computer, and that the computer image is not meant to show promised final results.

High patient satisfaction and low revision rates are obtained when surgeons spend quality time during the initial consultation discussing the patient's concerns and goals, along with their own expectations and limitations. This is a critical time in the physician-patient relationship; the surgeons must ensure that they understand their patients' desires and that patients understand what can and cannot be achieved. If the patient and surgeon are "on the same page" at the end of the consultation process and the surgeon thinks that he or she can provide the results that have been discussed, the likelihood of an optimal outcome is very high, and surgery can proceed.

ANESTHESIA AND PREOPERATIVE MANAGEMENT

Most patients undergoing rhinoplasty are treated on an outpatient basis with general anesthesia. Perioperative antibiotics are routinely given, but postoperative antibiotics are not necessary. The internal and external nose is infiltrated with local anesthesia consisting of a 50:50 mix of 1% lidocaine with 1:100,000 epinephrine and 0.25% bupivacaine with 1:200,000 epinephrine. Usually 2 to 5 ml is used and provides adequate pain control and vasoconstriction without causing excessive tissue distortion. Oxymetazoline-soaked (Afrin) pledgets are also packed into the nares to provide additional mucosal vasoconstriction. Patients typically receive 6 to 10 mg of intravenous dexamethasone intraoperatively, followed by a 6-day oral tapering dose of methylprednisone. The face is prepared with a gentle cleanser such as Cetaphil.

SURGICAL APPROACHES

Incisions and Approaches

Every surgeon has different comfort levels with open and closed approaches. In this chapter we will focus on the open approach, because it typically provides more exposure and control over the final outcome. Several different incisions are used for open rhinoplasties. We have found that a gull-wing incision heals better than a stairstep or straight transverse incision (Fig. 36-1). It should be placed at the midcolumnellar level above the medial crural feet and meet the vertical marginal incision at a right angle. A converse scissors is then used to elevate the soft tissue flap off of the medial crura (Fig. 36-2, *A*).

Fig. 36-1 Nasal anatomy and gull-wing incision.

Fig. 36-2 Flap elevation and harvesting of septal cartilage. **A**, A skin envelope is raised with uniform thickness. **B**, The central septum is harvested with a No. 15 blade. A 1 cm L-strut is preserved to prevent a saddlenose deformity and preserve tip support.

Septal Deformities and Cartilage Harvest

Septoplasty is typically performed first to fix any functional deformity and/or to harvest cartilage if necessary. If tip work is planned, the septum can be harvested through an open approach. However, if patients are satisfied with their tip characteristics, the cartilage can be harvested through a hemitransfixion incision to prevent disruption of the nasal tip supporting structures (which may introduce unwanted variability in tip aesthetics).

The anterior septal angle is easily identified through an open approach. The soft tissue between the medial crura can be removed to reduce fullness in the nasolabial angle. After the anterior septal angle is exposed, a No. 15 blade is used to make a small incision through the perichondrium on the septal cartilage to access the submucoperichondrial layer and allow easy flap elevation with a Freer elevator in an avascular plane. After both mucoperichondrial flaps have been adequately elevated, the septum can be harvested. A No. 15 blade is used to excise the central portion of the cartilage, leaving behind an L-strut that is at least 1 cm in width (see Fig. 36-2, *B*). The surgeon must take into consideration any dorsal hump resection that may be planned, because this will further reduce the dorsal L-strut. The wide exposure gives adequate access to remove any septal bony spurs, because these can cause significant airway obstruction.

Swinging-Door Flap

Patients with caudal septal deviation resulting from caudal septal base deflection off the maxilla frequently require a swinging-door flap.¹⁶ The caudal septal strut can be released from the maxilla, which will allow the inferior caudal septum to swing into the midline and rest in the maxillary groove. This may require excising 1 to 2 mm off the base to allow it to freely move to the midline without residual curvature. A caudal septal cartilage strut graft will provide additional support and structure to the caudal septum if necessary.

Septal Straightening Techniques

A crooked dorsal septum can create asymmetries of the brow-tip aesthetic line. These can be particularly difficult to correct. Several techniques can be used to correct or camouflage these deformities. Gentle scoring of the septal cartilage on the concave side will cause the cartilage to bend away from the scoring. Castellation or full-thickness incisions that weaken the septum will often disrupt the intrinsic bending forces (although if used should be reinforced with additional strut grafts to support the septum and hold it straight). Spreader grafts can also be employed to support a crooked septum and provide additional structural support. Often, a simple spreader graft is insufficient, and complete dorsal septal reconstruction is necessary. This may require complete excision of the native septum and dorsal septal graft reconstruction.¹⁷ Finally, onlay grafts can also be used to camouflage the defect.¹⁸

Nasal Tip Reconstruction

After the septal work has been completed, the major tip parameters should be set: length, projection, and rotation. I (J.P.W.) prefer to set these parameters first, and then shape the dorsum to match the ideal tip position already created. The tripod concept is applied when setting these parameters^{19,20} (Fig. 36-3). The tripod concept treats the lower lateral cartilage as a tripod, with each lateral crura representing one leg of the tripod, and the medial crura is the third leg. Shortening or lengthening a leg will affect the location of the tip. After these parameters are set, it is much easier to shape the dorsum in relation to the tip. Fine-tip sutures and additional grafting can be performed last to prevent disruption during dorsal manipulation. This approach provides predictable results.²¹

Fig. 36-3 Lower medial and lateral cartilage anatomy. The tripod theory treats each lateral crus and the paired medial crura as the legs of a tripod. Manipulation of each “leg” will affect tip position and projection.

Fig. 36-4 Lateral crural flap. **A**, The lateral crura have been released from the underlying mucosa and transected. **B**, The lateral crura are sutured together in an overlapped fashion with a Vicryl horizontal mattress suture. The flap is used to rotate the tip up and deproject the nose.

Nasal Length

Nasal length is determined by the distance from the nasofrontal angle to the tip-defining point. The nose can be shortened with two techniques: rotating the tip up and deepening the nasofrontal angle. Nasolabial augmentation can also make the nose appear shorter by increasing the apparent rotation. The tip can be rotated by shortening the lateral crura with the lateral crural flap technique (Fig. 36-4). The flap is usually only 2 to 3 mm in length but can vary depending on how much rotation is needed. The amount of flap overlap is measured bilaterally with calipers.

Fig. 36-5 Medial crural flap. **A**, The medial crura are measured and incised. **B**, Both medial crura have been overlapped and sutured together. **C**, This flap results in derotation and deprojection of the tip.

The lateral crura are cut near the middle and then overlapped, shortening the lateral crura. The cartilage flaps are sutured together with 5-0 Vicryl horizontal mattress sutures.

Short noses frequently have dorsal deficiency and require augmentation. Derotation, infratip lobule grafts, and nasofrontal augmentation will increase the length of the nose. Surgeons can also increase the apparent length of the nose by using dorsal onlay grafts and by deepening the nasolabial angle. Bilateral extended spreader grafts and caudal septal extension grafts may also be necessary to significantly lengthen a short nose.

Projection

Overprojection is one of the more difficult parameters to correct and is frequently neglected, leading to dissatisfaction. If the medial or lateral crura are too long, they should be shortened with lateral crural flaps and/or medial crural flaps. A medial crural flap procedure is similar to a lateral crural flap procedure, but the medial crura are incised near their cephalic one third (Fig. 36-5). Deprojection of the nasal tip can create alar base widening and alar flaring, which should be planned for and evaluated during surgery to determine whether soft tissue alar base reduction will be necessary.²² Potential soft tissue excision techniques of the alar base should be discussed with patients preoperatively, because additional external sutures and a scar will be present (although these scars heal incredibly well when the procedures are performed properly).

Underprojection is frequently a problem in nonwhite noses, particularly in blacks and peoples of Asian and Hispanic descent. Projection can be increased by columellar strut placement, transdomal suturing, lateral crural steal, and tip grafting.^{12,23,24}

Rotation

Tip-rotation issues can cause several different problems. An underrotated tip gives the appearance of a long nose. This can be caused by short or weak medial crura creating ptosis. A columellar strut can be sutured between the medial crura to provide support and rotate the tip up. It should extend down to the nasal spine to provide strength and support to the tip (Fig. 36-6). This can be secured by placing a horizontal mattress suture of 4-0 Vicryl on a Keith needle. The first pass should include both medial crura and the columellar strut graft, and the second pass goes behind

the columellar strut. As seen in Fig. 36-6, it is important to retract the nose with a double-prong skin hook to ensure that equal tension is placed on each dome.

An overrotated tip often creates excessive nostril show in the AP view, giving a “pig nose” appearance. This deformity can be corrected by several methods: an infratip lobule shield-type graft increases nasal length, shortening the medial crura and excising soft tissue at the nasolabial angle. Deepening the nasolabial angle in effect decreases the nasolabial angle, creating the appearance of a longer nose, and the tip rotation. In severe cases the supporting attachments from the tip and upper lateral cartilages and septum will need to be released and the tip rotated downward and secured in place with extended spreader grafts, thus forcing the tip down and keeping it in place.

Fig. 36-7 The lower lateral cartilages are trimmed along the cephalic margin, preserving the mucosa and 6 to 7 mm of rim for external valve support. The surgeon should preserve the upper lateral cartilage attachments to the septum at the nasal valve.

Cephalic Trim

Wide lateral crura can contribute to a widened bulbous appearance of the tip and supratip fullness. These deformities can be improved by a resection of the cephalic margin of each lower lateral cartilage (Fig. 36-7). The resection must be symmetrical and leave at least 6 to 7 mm of lateral crura to support the external nares and prevent external valve collapse.²⁵

DORSAL MANIPULATION

Dorsal Hump Reduction

Dorsal hump deformities are generally corrected after the major tip parameters are set. The dorsum can be shaped to match the tip projection and rotation (Fig. 36-8). The nasal dorsum is composed of the bony upper nasal vault and the cartilaginous middle nasal vault. When a nasal hump is present, the bony upper nasal vault is rasped to achieve a straight profile (Fig. 36-9). This should be done in a controlled, stepwise fashion, assessing progress throughout the procedure. The surgeon must not overresect the profile and create an unnatural appearance. If a component of cartilaginous dorsal excess at the middle nasal vault is also present, a sharp straight scissors or No. 11 blade can be used to achieve an ideal profile in this area. Prominent residual dorsal septal cartilage will result in a pollybeak deformity. A rasp will not remove the cartilage profile. Proper profile assessment requires the surgeon to squeeze out the edema with a cold wet sponge and sit on a stool to have a perpendicular view of the dorsal profile. Typically, altering the dorsal profile to remove a prominent hump will result in an open-roof deformity, which must be corrected with osteotomies (see Nasal Bone Osteotomies).

Fig. 36-8 A-C, Preoperatively this female patient thought that her nose was too big for her face, and she was unhappy with the nasal hump on profile view. She had nasal airway obstruction. D and E, Primary open septorhinoplasty was performed. The surgical steps included a septoplasty, excision of soft tissue at the nasolabial angle, tip deprojection with vertical lobular division (medial crural overlay), a columellar strut for tip stabilization, a bilateral cephalic trim, tip sutures, hump takedown, medial and lateral osteotomies, and bilateral spreader graft placement. F-H, The patient is shown 1 year postoperatively.

Fig. 36-9 Dorsal hump reduction. **A**, A rasp can be used for the bony component. **B**, A scalpel or straight scissors is used for the cartilaginous dorsal resection. **C**, It is essential to leave a smooth contour between the upper lateral cartilage and the septum after hump takedown is completed.

Dorsal Augmentation

Augmentation of the dorsum may be necessary to set a proper nasal height, correct a saddlenose deformity, and improve the dorsal nasal contour. If the dorsal height is too low, it can result in an overresected appearance. Autologous materials are preferred for dorsal augmentation. Septal cartilage can provide a strong, stable graft, but a large piece of cartilage or stacked cartilage grafts is often needed. Costal cartilage is frequently used.²⁶ The graft should be carefully sculpted to fit the defect, and the edges must be beveled to prevent visible step-off deformities and palpability. The graft must be secured to prevent malposition. We prefer to secure the graft to the nasal skin as described in the Onlay Grafts section. Saddlenose deformities are rarely encountered in patients who present for primary aesthetic surgery and are typically the result of trauma, previous surgery, or a congenital deformity.²⁷

Spreader Grafts

Spreader grafts are frequently used to increase the internal nasal valve angle, strengthen the dorsum if the L-strut is fractured, and straighten the dorsal aesthetic lines. These grafts are placed between the septum and upper lateral cartilage (Fig. 36-10). They should be sutured in place with

Fig. 36-10 Spreader grafts are useful to obtain optimal dorsal aesthetic lines and to open the internal nasal valve.

4-0 Vicryl horizontal sutures spanning the upper lateral cartilage, spreader graft, and the septum. At least two sutures are placed to prevent the graft from rotating out of position.

Nasal Bone Osteotomies

Nasal bone anatomy can be quite variable. Younger patients have much thicker bone compared with elderly patients. In patients with a history of trauma, the bone may be thick and callused. There are three indications to perform osteotomies: to straighten crooked nasal bones, to close an open-roof deformity that is frequently created from the dorsal hump reduction, and to narrow a wide upper third^{28,29} (Fig. 36-11).

Medial osteotomies are made first with a fading angle laterally to prevent a rocker deformity (seen when the medial osteotomies are carried straight up the bones). An open technique provides optimal exposure to visualize the placement of the osteotome. Additional local anesthetic is infiltrated in the internal nasal mucosa at the piriform aperture just superior to the head of the inferior turbinate in preparation for lateral osteotomies. A No. 15 blade is used to make a stab incision at this site. A Freer elevator can be used to create a subperiosteal tunnel for the osteotome, which helps to decrease bleeding. Curved, guarded osteotomes are used to make the lateral osteotomies in a high-low-high fashion, beginning superior to the inferior turbinate at the piriform aperture. If it is placed lower, it will cause the inferior turbinates to drop into the airway and obstruct the airway. The osteotomy is made in a curved fashion, aiming and ending medial to the medial canthus but not meeting all the way to the medial osteotomy (Fig. 36-12).

Fig. 36-11 A-C, Preoperatively this female patient's primary concerns were nasal obstruction and the appearance of the dorsal hump on profile view, and she thought that her nose was crooked. She did not want any major changes to her nasal tip. D and E, Primary open septorhinoplasty was performed. Surgical steps included septoplasty with submucous resection of cartilage and bone, dorsal septal reconstruction with a dorsal replacement graft, medial and lateral osteotomies, dorsal hump takedown, and a columellar strut to straighten and maintain the tip dynamics. F-H, The patient is shown 1 year postoperatively.

Fig. 36-12 Nasal bone osteotomies. Medial osteotomies are performed first; the surgeon is careful to not disrupt the septal nasal bone junction. Lateral osteotomies are started superior to the inferior turbinate and performed in a high-low-high fashion. The osteotome can be treated as a lever to assist in creating a greenstick fracture of the nasal bone medially.

On completion, the osteotome is used as a lever to create a greenstick fracture between the medial and lateral osteotomies, and the nasal bone is brought in medially in a controlled and stable fashion. If the nasal bones need to be widened, the same maneuvers are performed, and the bone is then lateralized and supported intranasally with a small piece of Surgicel.

NASAL FINE-TIP WORK

The nasal fine-tip work should be done toward the end of the procedure. This will decrease the chance of disrupting fine suture and graft placement during dorsal maneuvers.

Tip Sutures

A single-dome unit-binding suture (intradomal) can be used to create individual refinements to each dome, set the exact tip position and angle, and create more definition.¹² The use of this suture can ensure that both tips have a similar anatomic shape. A double-dome unit-binding suture (interdomal) can be placed between the domes to medialize the domes, narrow the tip, and bring the domes together to a symmetrical height.²³ These maneuvers can also increase the tip projection. Another commonly used tip suture is an intermediate crural horizontal mattress suture. This suture can strengthen the medial crural–columellar strut complex and narrow the infratip columella to decrease a hanging infratip. All of these techniques should be done in a stepwise fashion, continuously assessing their impact on the overall nasal appearance.

Fig. 36-13 Nasal tip shield grafts are placed to add length or rotation when needed. Tip grafts are best secured to the nasal cartilaginous skeleton.

Tip Grafts

Tip grafts can be used to camouflage asymmetries, increase nasal projection, and increase or decrease tip rotation, depending on the location. Grafts need to be meticulously shaped to fit the desired defect and to effect an exact change. The edges must be beveled to ensure that there are no palpable step-offs that may become visible when the swelling decreases. Most tip grafts are best secured directly to the nasal skeleton with 6-0 sutures.

An infratip graft placed just below the domal angle will add fullness and definition to the infratip region (Fig. 36-13) and result in an apparent derotation of the tip. A cap graft can be placed spanning both domes to add projection or definition. They can also be placed over a single dome to provide better domal symmetry.

Lateral Crural Strut Grafts

Lateral crural strut grafts are commonly used in patients who present with external valve collapse or misshaped native cartilages resulting in deformity. These grafts are optimally created from strong septal or rib cartilage to provide the necessary strength. They are typically placed under the native lower lateral cartilage (between the cartilage and mucosa) but can also be placed in an onlay fashion. The medial aspect should not extend past the domal apex, and a smooth transition laterally is essential to prevent graft visibility after swelling subsides.³⁰

Onlay Grafts

Before final closure, the nasal sidewalls and dorsum are assessed for any irregularities or asymmetries that could lead to a suboptimal outcome. Deformities of this type can be corrected by placing a dorsal onlay graft. This is done after all of the maneuvers have been completed, because very fine grafts will usually need to be created. Unlike tip grafts that are sutured to the nasal skeleton, dorsal onlay grafts can usually be more precisely secured with a percutaneous horizontal mattress suture through the skin and graft. The suture should be tied securely but should not indent the skin to prevent ischemia as postoperative swelling develops (Fig. 36-14).

Fig. 36-14 A-C, Preoperatively this female patient thought that her nose was too big for her face. She had nasal airway obstruction. D and E, She had a primary open septorhinoplasty, which included septoplasty (with submucous resection and caudal base repositioning), dorsal septal reconstruction with a replacement graft on the left side, right spreader graft placement, tip deprojection with vertical lobular division (medial crural overlay), stabilization of the tip with a columellar strut, tip sutures placement, excision of soft tissue at the nasolabial angle, cephalic trim, dorsal hump takedown, medial and lateral osteotomies, and dorsal sidewall onlay grafting. F-H, She is shown 1 year postoperatively.

FINAL REFINEMENTS: EXCISION SOFT TISSUE TIP TECHNIQUES

Excessive width of the lower third of the nose may be apparent on preoperative evaluation or may become obvious only when a tip is changed during surgery. Surgeons should point out these potential issues to patients and offer solutions that can create a well-balanced and aesthetically pleasing result.

Alar Base Surgery

The alar base has two components: a cutaneous ala portion and a vestibular surface. These can be managed independently to cause varying degrees of changes to the alar width and nostril size²² (Fig. 36-15). The optimal position for the incision is along the natural curve of the nasal sill to prevent unsightly scars. The nasal margin excision will determine the effect on the nostril and alar base. An external alar base reduction with an inverted-V resection can be used to reduce the columellar-alar base distance and the apparent nasal width. An internal alar base reduction with a V-shaped resection will narrow the nostril circumference but maintain the nasal width. Alternatively, to decrease the base width and nostril size, a square-shaped piece should be resected from the nasal margin.

Fig. 36-15 Soft tissue resections of the alar base. **A**, External alar base excision. The excision is planned as an inverted-V to not disturb the circumference of the nostril margin. **B**, Internal base excision. Isolated excision of the nostril margin reduces only the nostril circumference while leaving the columellar-alar base distance unchanged (thus preserving the alar base width). **C**, External and internal base excision. **D**, Alar flare reduction. A segment of tissue is removed from around the alar base to reduce the tip-alar base distance, thus shortening that limb and making the ala straighter.

Alar Flare Reduction

After the alar base width and nostril size have been addressed, the flaps are mobilized and advanced medially in position with one stitch. Alar flaring can then be assessed and managed. This is best done in the basal view. Ideally, the alae should be relatively straight from the nasal tip to the base. If they are excessively flared or convex, excising a portion of the alar base and shortening the distance can straighten them.²² These incisions are closed with 6-0 nylon interrupted sutures.

Alar Hooding Reduction

Alar hooding is seen when the alae hang excessive low and cover the columella in the profile view. In these patients, an idealized alar curvature is drawn, and an elliptical excision is made along the border of the nostril margin. The incision should be along the visual border, because these tend to heal well.²² The incision is closed with 6-0 running nylon sutures.

CLOSURE

The columellar incision is closed with simple 6-0 nylon sutures. The junction at the transverse columellar and vertical marginal incisions is at the most risk for poor scarring resulting from a trap-door effect. Minor undermining of the columellar skin on the lateral aspect of the columella and placement of a partial-thickness suture superiorly and a full-thickness suture inferiorly to tuck in the superior flap edge decrease the risk of the trap door effect. The marginal incisions are closed with 4-0 chromic suture. Care is needed to not distort the alar rim, because this can create unfavorable scarring.

Silicone septal splints are placed to stabilize the septum and secured with a 4-0 Vicryl transfixion suture. Nasal packing is unnecessary, because it typically is extremely uncomfortable for the patient and provides no benefit. If osteotomies are performed, an Aquaplast cast is placed to stabilize the nasal bones.

POSTOPERATIVE CARE

Patients are provided with narcotic pain medications and instructed not to start NSAIDs or aspirin products until 48 hours after surgery. Oral steroids are given in a 6-day tapered dose. Oral *Arnica montana* is also used to decrease bruising. Patients are encouraged to keep their heads elevated and to aggressively ice the area. They are instructed not to engage in physical activity for 3 weeks and contact sports for 6 weeks.

Sutures are removed from the columella 4 to 5 days postoperatively, and small Steri-Strips are placed and removed after 4 days. The cast and splints are removed 7 to 8 days after surgery. Patient follow-up is at 3 weeks, 3 months, 6 months, and 1 year. Standardized photographs are taken at each follow-up appointment.

MANAGEMENT OF COMPLICATIONS

Careful preoperative planning and surgical technique with conservation of the tissue can minimize postoperative complications. In general, the complication rate from rhinoplasty surgery can be quite low, but complications will arise. Surgeons must be supportive and responsive to patients' concerns.

Complications range from postoperative hematomas and infection to aesthetic deformities that are frequently more difficult to treat and may require revision operations.³¹ Both moderate swelling and periorbital ecchymosis are expected but can be minimized with constant icing, *A. montana*, and steroids. Mild postoperative oozing is expected and can be controlled with a mustache dressing for 24 to 48 hours. More moderate bleeding can be managed with head elevation and ice on the back of the neck. More serious bleeding may require reexploration in the operating room. Unrecognized septal hematomas can lead to cartilage necrosis and loss of support. The risk of septal hematoma can be decreased by placing horizontal mattress sutures in the septum to reduce dead space and by creating a small, unilateral stab incision in one (not both) of the mucoperichondrial flaps to allow blood to drain.

Infections are rare but can range from mild cellulitis to abscess formation.^{31,32} Early identification and treatment are essential to prevent tissue necrosis and potential toxic shock syndrome.³³ Mild cellulitis will normally respond to cephalosporins. If the cellulitis persists or worsens, admission for IV antibiotics may be appropriate.

Postoperative deformities may commonly result from underresection or overresection of the osteocartilaginous framework, unrecognized asymmetry at the time of surgery, postoperative bone movement, cartilage resorption, scar tissue formations, cartilage warping, and poorly shaped grafts with edges or graft migration resulting from securing issues.³¹ A suboptimal outcome can occur for other reasons. Typically, major deformities recognized early do not improve over time. However, frequently, with more minor deformities, what appears to be a deformity may actually be the result of swelling, and patient waiting is always prudent. Patients can attempt to perform molding techniques to manually shape the cartilage by applying controlled pressure on the defect for 5 minutes, five times a day, for 5 weeks. Taping and massage may also help. Revision operations can be considered for persistent defects present for more than 1 year. For a patient who is concerned about a persistent deformity after 1 year, the surgeon should correct the deformity if he or she thinks this is possible.

CONCLUSION

Adolescence is a critical period of both physical and mental development, and self-image can be adversely affected by nasal deformities. Adolescent rhinoplasty can result in gratifying outcomes that greatly enhance a patient's psychosocial well-being. In many patients, functional and aesthetic improvement can be achieved. A thorough preoperative evaluation and discussion of expectations, coupled with computerized imaging, can prevent misunderstandings that lead to postoperative disappointment. A stepwise approach to nasal surgery is important, with an emphasis on a conservative but thorough approach to each patient's aesthetic and functional needs. By following these steps, surgeons can fully address their patients' concerns in a logical and systematic fashion to obtain the best possible outcome.

KEY POINTS

- The nose is the focal point of facial aesthetics; therefore it is a key component in establishing harmonious facial balance.
- An adolescent's self-esteem is greatly influenced by physical appearance.
- For all patients undergoing rhinoplasty, especially adolescents, communication between the patient, parents, and plastic surgeon is essential for a successful result. Reasonable expectations must be discussed preoperatively with the patient and family.
- A stepwise approach to rhinoplasty is recommended, allowing a sequential surgical treatment plan that is predictable and reproducible.
- Surgeons should define the tip parameters (length, projection, and rotation) and then match the dorsum to the tip.

Pediatric Head and Neck Masses

Erin M. Rada • Amir H. Dorafshar

Pediatric head and neck masses are a heterogeneous group of lesions of various etiologies. Diagnosis of these lesions can be challenging for several reasons. First, not all lesions are readily apparent, and children may be unable to adequately communicate their symptoms. Second, with such a diverse group of pathologies, practitioners may not have first-hand experience with many of these diagnoses. Finally, the anatomy of the head and neck region is a complex, dense network of vital structures. In children the size and proportion make physical examination more difficult.

Head and neck masses in children may be classified by their anatomic location, age at presentation, and cause. In this chapter, we will categorize lesions as congenital, infectious, inflammatory, and neoplastic.

PATIENT HISTORY, PHYSICAL EXAMINATION, AND IMAGING

To diagnose pediatric head and neck lesions, we begin with a thorough history and physical examination. Obtaining a history involves getting patients' and/or their caregivers' account of symptoms. Information gleaned should include onset of mass appearance, location, growth, associated local and constitutional symptoms, recent illness, sick contacts, recent travel, contact with animals, trauma, vaccination record, drug use, a personal or family history of cancer, and head and neck pathology.

The timing of the onset of symptoms may help to identify a congenital lesion and narrow a patient's differential diagnosis. Surgeons should keep in mind, however, that many congenital lesions present at birth are not noticed until later in infancy or childhood. Temporal relationships and changes over time are also important with acquired lesions. Some infectious and inflammatory lesions such as cervical lymphadenopathy may be preceded by a recent upper respiratory tract illness or other recent exposure. The rate of growth of neoplasms alerts practitioners to aggressiveness of the tumor. The location and laterality provide further clues for diagnosis.

In a physical examination, the appearance of a lesion at rest and with diagnostic maneuvers such as swallowing is noted. Associated skin changes such as erythema and overlying punctum are observed. On palpation, lesion texture and depth and adherence to underlying structures or skin may be appreciated.

Imaging is an important adjunct to a history and physical examination to help determine a diagnosis and to better understand the anatomic relationship for preoperative surgical planning. For most neck lesions and many head lesions, ultrasonography may be used as a first-line imaging modality. The advantages of using ultrasonography are that it is noninvasive, does not typically require sedation, delivers no radiation, and is able to distinguish cystic from solid lesions. The disadvantages include variability in results based on the ultrasonographer's skill and the inability to provide detailed soft tissue differentiation. CT and MRI are also frequently used. CT is particularly good at demonstrating bony pathology, whereas MRI provides superior soft tissue definition.

Treatment varies by the type of lesion. In general, congenital lesions may be managed surgically, and infectious and inflammatory lesions are treated medically. Treatment for neoplastic lesions is mixed. Some treatment protocols include chemotherapy and radiotherapy. In those cases, surgeons may still be called on to obtain tissue from an open tissue biopsy for diagnostic or staging purposes. Many treatment protocols include surgical tumor resection with or without subsequent adjuvant therapy.

CONGENITAL LESIONS

Congenital lesions make up a significant proportion of pediatric head and neck masses. In some series they are the most common cause of these lesions.¹ Despite their presence at birth, many of these lesions go undiagnosed until they become acutely inflamed, often later in infancy or childhood. With the improvement in imaging technology, congenital head and neck lesions are increasingly diagnosed in the prenatal period on routine ultrasonography. Prenatal MRI may be used to further characterize these masses. In addition to preparing parents for an eventual diagnosis, this information may be used to plan early intervention that can be lifesaving. If a head and neck tumor is diagnosed prenatally and considered potentially airway compromising, surgeons may perform an ex utero intrapartum treatment (EXIT) procedure. In an EXIT procedure, a modified cesarean delivery is performed. The baby is partially delivered and may undergo various procedures before separation from the umbilical cord and placenta. This allows continued oxygenation through the maternal circulation. In infants with head and neck masses, this is most frequently used as a means to secure the airway in a controlled fashion rather than emergently after delivery.

Vascular Malformations

Vascular malformations are lesions involving the vascular system that are present at birth and grow in proportion to the infant. They may or may not be visible at birth or in infancy and may remain quiescent or gradually enlarge. They are typically made up of mature vessels and can be classified based on vessel type and flow characteristics. They need to be distinguished from hemangiomas, which more commonly appear after birth and grow out of proportion to overall growth. Vascular

malformations are discussed in Chapters 11 and 13; however, because they are frequently part of the differential diagnosis of head and neck lesions, we also discuss them here.

Lymphatic malformations are highly variable, slow-flow vascular malformations that are characterized by disorganized, dilated lymphatic channels. The high concentration of lymphatics in the head and neck region explains why 75% of these malformations occur in this region. Previously known as *cystic hygroma* and *lymphangioma*, these are the most common vascular lesion affecting the head and neck region.² They may be classified as macrocystic (≥ 2 cm spaces), microcystic, or mixed (Fig. 37-1). Clinical staging is based on anatomic location³ (Box 37-1).

Fig. 37-1 A and B, A macrocystic lymphatic malformation seen in preoperative and intraoperative views. Although sclerotherapy may be the treatment of choice, surgery may be indicated. The large cysts of the malformation are readily visible here. C and D, A microcystic lymphatic malformation of the cheek, which is most easily diagnosed by the presence of fine lymphatic vesicles on the labiobuccal surface. E, A macrocystic lymphatic malformation replacing the entire right temporalis muscle and presenting with acute bleeding into the malformation. F, At resection.

Box 37-1 Lymphatic Malformation Stages of de Serres et al

- III. Unilateral suprahyoid and infrahyoid lesion
- IV. Bilateral suprahyoid lesion
- V. Bilateral suprahyoid and infrahyoid lesion

Fig. 37-2 A, Preoperative appearance of a 5-year-old girl with a lymphatic malformation of the right side of her face. She is shown after several attempts at sclerotherapy with limited improvement. B, Wide exposure with preauricular incision, intraoperative nerve monitoring, and a visible lymphatic malformation. C, The specimen after partial excision. D, Postoperatively, the patient has improved facial contour and facial nerve preservation.

Patients with lymphatic malformations typically present at birth or in early infancy with a soft, spongy, painless mass that transilluminates. Some patients may be diagnosed prenatally with routine ultrasonography, whereas other diagnoses are delayed until later childhood when an inciting infectious or inflammatory event makes the lymphatic malformation obvious. Because the size of these lesions varies significantly, they are associated with a variety of presentations, ranging from completely asymptomatic to causing bony or soft tissue overgrowth and airway compromise. CT/MRI is used to characterize lesions and delineate relevant anatomic location.

In the past, surgical excision was the treatment of choice for lymphatic malformations. Currently, sclerotherapy is more frequently used as first-line therapy for these lesions, particularly for macrocystic and mixed disease. Sclerotherapy is not as effective for microcystic disease. When surgical resection is attempted, intraoperative nerve monitoring may be useful during dissection, and subtotal resection may be necessary to preserve important structures (Fig. 37-2).

Branchial Cleft Lesions

The branchial arches and associated clefts and pouches develop in the fourth week of gestation. Initially there are six paired arches, but the fifth arch quickly involutes. The remaining arches are associated with an external cleft and an internal pouch. Each arch is lined internally by endoderm and externally by ectoderm and contains mesodermal elements, which give rise to nerve, arterial, and skeletal structures⁴ (Table 37-1).

Table 37-1 Branchial Arch and Associated Derivatives

Derivatives of Pharyngeal Folds	Arch Number	Cranial Nerve	Muscles	Skeletal	Artery
External auditory meatus	I. Mandibular	V. Trigeminal	Muscles of mastication, mylohyoid, anterior belly of digastric, tensor palatini, tensor tympani	Premaxilla, maxilla, Meckel's cartilage, squamous temporal bone, malleus, incus, sphenomandibular ligament	Maxillary
Neck	II. Hyoid	VII. Facial	Muscles of facial expression, buccinator, platysma, posterior belly digastric, stylohyoid, stapedius	Stapes, stylohyoid process/ligament, part of hyoid cartilage	Hyoid, stapedial
	III.	IX. Glossopharyngeal	Stylopharyngeus muscle	Part of hyoid cartilage	Common/internal carotid
	IV.	X. Vagus (Superior laryngeal)	Cricothyroid muscle, soft palate musculature (except tensor veli palatini)	Thyroid cartilage, parathyroids, epiglottis	Right subclavian, aorta
	VI.	X. Vagus (Recurrent laryngeal)	Laryngeal musculature	Cricoid, styloid, corniculate cartilage	Pulmonary, ductus arteriosus

Branchial cleft anomalies are one of the most common types of congenital neck lesion and include cysts, internal sinuses, external sinuses, and fistulas. The most common of these are *branchial cleft cysts*, which are congenital, epithelium-lined cysts that form on pathologic or incomplete fusion of two adjacent arches. These lesions are relatively common, composing as much as one third of all pediatric neck lesions. They arise in predictable locations that are dependent on which arch is involved (Fig. 37-3). No ethnic or gender association has been reported for these lesions.

Although these are congenital lesions, they are not always diagnosed at birth. Many patients with branchial cleft cysts are diagnosed in childhood or even adulthood when the cyst becomes inflamed, frequently after an upper respiratory tract infection. Patients may present with pain, swelling, erythema, dysphagia, dyspnea, drainage, otorrhea, or halitosis, depending on the cyst location. In addition to a history and physical examination, imaging is useful in diagnosing branchial cleft cysts. Ultrasonography is a first-line imaging modality to diagnose these cystic lesions, whether a cyst or sinus tract is appreciable on physical examination. CT/MRI may show further definition of the lesion and demonstrate its relationship to the surrounding structures.

First Branchial Cleft Cysts

First branchial cleft cysts are rare, composing less than 10% of all branchial arch lesions.⁵ There are several classifications of these lesions, including the *Work classification*, which describes these lesions as type I and type II.⁶ Type I lesions are of ectodermal origin and thus are lined with squamous epithelium. Their location parallels the external auditory canal, with a possible fistula opening in the postauricular or pretragal region. The facial nerve is not typically involved (Fig. 37-4). Type II lesions are more common than type I lesions. Both are of ectodermal and mesodermal origin and therefore may contain squamous epithelium and cartilage. Type II lesions are typically found between the external auditory canal and neck, superior to the hyoid bone. The facial nerve and parotid gland are more intimately associated with these lesions than with type I lesions (Fig. 37-5). If possible, the treatment of both of these lesions is surgical excision if inflammation is not present. Wide exposure through a preauricular parotidectomy incision is preferred for adequate visualization and avoidance of the facial nerve (Fig. 37-6). Superficial parotidectomy may be necessary to completely remove these lesions and preserve the facial nerve. Intraoperative nerve monitoring is often used, because the normal anatomy may be distorted as a result of the lesion.

Fig. 37-4 A type I lesion of the first branchial sinus tract presenting as a preauricular pit. At excision, the sinus tract extends to the helical crus, where a segment of cartilage must be resected to prevent recurrence.

Fig. 37-5 A, A cervicoauricular cyst and sinus tract extending to the external auditory canal. B, A segment of the cartilage must be resected with the sinus tract to prevent recurrence.

Fig. 37-6 A, A first branchial cleft fistula. B, Exposure, superficial parotidectomy with seventh cranial nerve dissection. The probe is in the fistula tract.

Second Branchial Cleft Cysts

Second branchial cleft cysts are by far the most common branchial pathology, accounting for 90% of these lesions. The second branchial arch contributes the future hyoid bone, and these lesions are located in the neck, inferior to the hyoid. If a cutaneous fistula is present, the opening is typically found along the anterior border of the sternocleidomastoid muscle (SCM). It then travels deep to the platysma and deep and posterior to the submandibular gland, between the internal and external carotid arteries, and over the hypoglossal and glossopharyngeal nerves to terminate in the tonsillar fossa (Fig. 37-7). A cyst may be present anywhere along this path. Historically, these cysts have been described by anatomic location, according to the Bailey classification^{7,8} (Box 37-2). The isolated second branchial arch cyst typically presents laterally in the neck below the angle of the mandible without a sinus tract and in most patients does not present until adulthood (Fig. 37-8).

Although anomalies of the remaining branchial arches exist, they are exceedingly rare, accounting for less than 2% of branchial cleft cysts. Because of their location, these lesions may be confused with suppurative thyroiditis or other thyroid pathology.⁹

Third Branchial Cleft Cysts

Third branchial cleft cysts begin at the piriform aperture and then travel superior to the superior laryngeal nerve and between the hypoglossal and glossopharyngeal nerves. Most often, they are found posterior to the SCM in the posterior cervical space. They are more commonly found on the left side.

Fourth Branchial Cleft Cysts

Fourth branchial cleft cysts begin at the piriform sinus but travel inferior to the superior laryngeal nerve and down the tracheoesophageal groove.¹⁰ Third and fourth branchial cleft cysts typically cannot be distinguished radiographically. Differentiation is largely based on the relationship to the superior laryngeal nerve and thus is made intraoperatively.

Fig. 37-7 A-D, This bilateral second branchial cleft cyst and sinus presented with the cyst alone in the right side of the neck but with the sinus tract opening in the typical location at the anterior border of the SCM at the junction of the mid and lower third of the muscle. Here, it was resected through a single incision. E and F, The entire embryologic tract can be seen with canalization of the tract extending into the pharynx. This was excised through the often-described *stairstep incisions*.

Fig. 37-8 An isolated second branchial cleft cyst in a young child.

Box 37-2 Bailey Classification of Second Branchial Cleft Cysts

Type I. Most superficial; lies deep to the platysma and anterior to the SCM

Type II. Most common; lies anterior to the SCM, lateral to the carotid space, posterior to the submandibular gland, and adherent to the great vessels

Type III. Extends medially between the external carotid artery and internal carotid artery to the lateral pharyngeal wall

Type IV. Lies within the pharyngeal mucosal space

Fig. 37-9 This midline branchial vestige was not associated with a sinus tract but had an underlying amorphous cartilage vestige and a fibrous tract to muscle in the midline.

Treatment

Surgery is the mainstay of treatment of the second, third, and fourth branchial cleft cysts. Horizontal stairstep incisions placed in natural neck creases may be used to identify and resect the cyst and/or fistula tract in its entirety, although resection through a single incision is possible in some patients (see Fig. 37-7). The surgeon must be careful to avoid cranial nerves IX through XII during this dissection, particularly when small stairstep incisions are used and visibility is limited. Patients with an inflamed lesion can be given a course of antibiotics, with or without lesion aspiration, to decrease the local inflammation in preparation for surgical excision.

Branchial Cartilaginous Remnant or Cartilaginous Rests

Branchial cartilaginous remnants or *cartilaginous rests*, although considered lesions of the branchial apparatus, are far less common than branchial cleft cysts and sinuses. They are cervical deposits of cartilage most frequently found at the anterior border of the SCM and can be unilateral or bilateral. They are usually diagnosed in infancy. Affected patients present with asymptomatic masses in the neck that contain palpable cartilage within their substance. Treatment is surgical excision¹¹⁻¹³ (Fig. 37-9).

Thyroglossal Duct Cysts

Thyroglossal duct cysts (TDC) are the second most common congenital neck lesions after branchial cleft cysts. The thyroid gland begins developing in the third week of gestation; it starts as an epithelial invagination at the foramen cecum and makes its descent anterior to the hyoid to its adult position anterior to the larynx. Thyroid gland development is completed by the eighth week of gestation, and the tract is normally obliterated in the following 2 weeks. However, if epithelium persists at any point along the tract, a TDC may form.¹⁴

Approximately half of patients with TDCs present before 20 years of age.⁵ A typical presentation of these lesions is a child with an asymptomatic midline neck mass overlying the hyoid, but these lesions have the potential to become inflamed or infected (Fig. 37-10). A history and physical examination are generally adequate to diagnose a TDC. They can best be seen with the patient's neck extended and should elevate with swallowing or tongue protrusion. The patient's normal

thyroid gland should be examined to verify its presence. If further imaging is desired for evaluation of the lesion itself or the native thyroid gland, ultrasonography is the modality of choice. When a normal thyroid gland is detected on physical examination or imaging, a thyroid scan is not required. If, however, a normal thyroid gland is not detected, a TDC must be differentiated from ectopic thyroid tissue. As much as 10% of ectopic thyroid tissue is found in the neck, and in most of these patients, it is the only functioning thyroid gland.

Management of these lesions is surgical excision with the Sistrunk procedure. Sistrunk¹⁵ first described this procedure in 1920. It involves a small, transverse incision over the cyst, followed by excision of the cyst itself along with the tract from the tongue base to the thyroid gland and the central third of the hyoid bone¹⁶ (see Fig. 37-10). The Sistrunk procedure has repeatedly shown a lower incidence of recurrence than less aggressive techniques such as cyst-only excision.¹⁵

Fig. 37-10 A, A TDC is visible with traction on the midline neck. B, The tract at resection. C, Excision of the TDC, tract, and central hyoid in a Sistrunk procedure. D, A residual TDC shown at repeat surgery, with the cyst constricted centrally by hyoid tissue not resected initially with the Sistrunk procedure.

Dermoid Cysts

The term *dermoid cysts* may be used to describe several different lesions, including dermoid cysts, epidermoid cysts, and teratomas. These lesions differ in their composition and embryologic origin. Epidermoid cysts arise from ectodermal tissue, dermoid cysts from ectodermal and mesodermal tissue, and teratomas from all three germ layers. Dermoid cysts are commonly encountered congenital masses, accounting for 60% of all facial cysts.¹⁷ These cysts are frequently located along sites of embryologic soft tissue or bony fusion. In the head and neck region, this includes periorbital, nasal, intraoral, anterior and posterior fontanelles, and postauricular sites of formation (Fig. 37-11). They are lined with stratified squamous epithelium and may contain hair follicles and other dermal appendages.

Patients with dermoid cysts typically present with a painless, firm, palpable mass that does not transilluminate or change with crying. However, they may become infected, in which case patients may present with signs of infection and inflammation. For dermoid cysts not occurring in the midline, diagnosis may be based on clinical examination, and no further imaging is required. Midline nasal dermoid cysts require investigation into possible intracranial communication. (See Chapter 35 for further discussion of nasal dermoid cysts.)

Dermoid cysts are treated by complete surgical excision, preventing cyst rupture when possible. Underlying adherent periosteum should be included in the resection specimen. Incomplete excision is acceptable in patients in whom the cyst is adherent to vital structures.¹⁸ Patients should be monitored for cyst recurrence, especially in incompletely resected lesions.

Teratomas

Teratomas are rare germ cell tumors that are derived from all three germ layers: ectoderm, mesoderm, and endoderm. They develop from aberrant pluripotent cells that stray in the fourth to fifth week of gestation. They may be classified as mature or immature, depending on the tissue type present. Mature teratomas account for most pediatric teratomas. Mature teratomas contain well-differentiated cells and structures, and they are associated with elevated levels of alpha-fetoprotein. Immature teratomas are poorly differentiated and contain embryonal elements. They have a significantly higher risk of malignant transformation and are also associated with elevated beta-human chorionic gonadotropin.

Fig. 37-11 An external angular dermoid cyst located at the zygomaticofrontal suture. **A**, The most common presentation is either a fixed or mobile cyst at the lateral orbit. **B** and **C**, At excision, this cyst is positioned in a concavity in the orbital bone at the frontozygomatic suture.

Head and neck teratomas account for 2% to 5% of all germ cell neoplasms and include cervical and craniofacial teratomas.¹⁹ They are frequently diagnosed with prenatal ultrasonography. They appear as large semicystic lesions and may be difficult to distinguish from a lymphatic malformation or branchial cleft cyst. Polyhydramnios may also be seen on prenatal ultrasonography as a result of the fetus's impaired ability to swallow because of the mass effect of the lesion. Diagnosis can be further investigated with fetal MRI.

Treatment

Treatment of these lesions, whether mature or immature, is surgical excision. The EXIT procedure may be performed for lesions diagnosed prenatally to secure the patient's airway in preparation for tumor excision. Tumor excision is ideally performed in the first 48 hours of life or after diagnosis to prevent complications associated with airway impingement by the lesion itself or loss of airway with a hemorrhagic event. For aggressive, immature lesions, chemotherapy may be considered. The prognosis is excellent for patients who undergo successful airway stabilization and tumor resection (Fig. 37-12).

Fig. 37-12 A, A teratoma of the vomer, resulting in a cleft palate. B, The resected teratoma. C, The cleft of the secondary palate. D, The repaired palate 5 years after repair.

Heterotopic Neuroectodermal Tissue

Heterotopic neuroectodermal tissue comprises a group of lesions that includes encephaloceles and gliomas. Both present with craniofacial masses in various locations—most commonly occipital and anterior (sincipital) (in the glabellar region). Although benign, these lesions may be disfiguring and are treated by surgical excision to prevent further craniofacial distortion. (See Chapter 39 for further discussion of encephaloceles and gliomas.)

Congenital Muscular Torticollis and Pseudotumor of Infancy

Congenital muscular torticollis (CMT) and *pseudotumor of infancy* (POI) are musculoskeletal conditions characterized by unilateral shortening of the SCM with or without palpable intramuscular mass. As a result, contralateral face/chin rotation and ipsilateral head tilt occur.^{20,21} It is unclear whether these two conditions are pathologically distinct, but most commonly POI refers to an intramuscular neck mass that develops by 6 weeks of age, whereas CMT results after 6 weeks. The cause of CMT and POI is not well understood. Theories have been published proposing intrauterine fetal positioning, birth trauma, and familial inheritance as the causes of the disorder.²² The diagnosis of these conditions may be made clinically. If further confirmation is needed, ultrasonography is the imaging modality of choice and may demonstrate a fibrotic lesion of heterogeneous echogenicity. Fine-needle aspiration with interstitial fibrosis may also be performed to confirm the diagnosis, but this is unnecessary in most cases.²⁰ Initial management consists of massage and passive range-of-motion exercises performed at home by the child's family or if this is unsuccessful by physical therapists. If successful, some improvement should be noted by 8 weeks, but on average the duration of therapy for maximal benefit is 4 months. In most cases (90%), physical therapy is successful, but if no improvement is noted, surgical intervention consisting of open or endoscopic disinsertion of the sternal and clavicular heads of the SCM should be considered. Varying success with botulinum toxin injection directly into the affected muscle has been described.^{1,23-25}

Cervical Thymic Cysts

Cervical thymic cysts are rare congenital pediatric neck masses. Beginning in the third week of gestation, the thymus gland develops from the third branchial pouch and descends into its final resting place in the mediastinum. Cervical thymic cysts can occur with implantation of thymic tissue anywhere along this tract, from the angle of the mandible to the mediastinum. Regardless of location, they frequently have some connection to the mediastinum.²⁶ These cysts are usually diagnosed in patients younger than 20 years of age.²⁷

Patients typically present with a painless lateral neck mass, usually on the left side. In unusual cases these lesions may be sufficiently large so that they cause stridor, dyspnea, hoarseness, and dysphagia. On physical examination, they appear similar to branchial cleft cysts both in appearance and location. Ultrasonography may reveal a unilateral, unilocular, or multilocular cyst in the lateral neck and inferior extension into the mediastinum. Surgical excision is the treatment of choice for these lesions. Diagnosis relies on a tissue sample obtained at surgical excision of the cyst.

CONGENITAL OR ACQUIRED LESIONS

Ranulas

Ranulas are submucosal extravasation of sublingual salivary glands. They may be congenital or acquired. Congenital ranulas may result from an imperforate sublingual salivary gland duct and frequently resolve spontaneously. Acquired ranulas are often the result of trauma to the duct and are more likely to recur if no intervention is performed. They may be classified based on anatomic location as either simple or plunging ranulas. Simple ranulas are confined to the floor of mouth, whereas plunging ranulas extend through a natural separation in the mylohyoid muscle into the neck.²⁸ Although typically asymptomatic, these lesions may cause tongue elevation or dysphagia if they are of sufficient size. On physical examination, simple ranulas appear as a fluctuant, blue-tinged dome in the floor of mouth that will transilluminate. Plunging ranulas may appear as a soft, fluctuant neck mass of varying size. Various imaging modalities have been used to diagnose these lesions, including ultrasonography, CT, and MRI. The lesion contents may be aspirated for diagnostic purposes and will yield amylase-rich fluid. Treatment for ranulas includes observation, marsupialization, incision and drainage, sclerotherapy, sublingual salivary gland lobe resection, and radical resection of the sublingual gland. Of these, resection of the entire sublingual gland through either the intraoral or transcervical approach is most likely to result in the lowest chance of recurrence.^{29,30}

ACQUIRED LESIONS

Infectious Lesions

Infectious causes of acquired head and neck masses can create acute enlargement of the regional lymph nodes or salivary glands. Most acquired head and neck masses in the pediatric population are inflammatory or infectious. Infections may be bacterial, viral, or fungal. In investigating a pediatric head or neck mass, surgeons should obtain a thorough history from the patient or caregivers; special attention should be paid to the temporal relationship of mass and infection, recent travel, exposure to animals, sick contacts, vaccination history, trauma, associated symptoms, and drug use. Although a clinical diagnosis, laboratory tests, including cultures and imaging, may often help to determine a definitive diagnosis.

Sialadenitis

Sialadenitis is the inflammation of any of the salivary glands. Bacterial sialadenitis is most common in infants younger than 2 months of age. Infection is typically polymicrobial, with *Staphylococcus aureus* most often isolated. *Haemophilus influenzae*, *Peptostreptococcus*, *Streptococcus pneumoniae*, *Escherichia coli*, *Bartonella henselae*, and *Bacteroides* are also culprits. Viral sialadenitis may be caused by mumps, Epstein-Barr virus, cytomegalovirus, adenovirus, influenza, herpesvirus 6, parainfluenza, coxsackievirus, or human immunodeficiency virus. Granulomatous diseases may affect the salivary glands through the periglandular lymph nodes. Atypical mycobacteria, tuberculosis, actinomycosis, and sarcoidosis are causative organisms.

If infectious sialadenitis is suspected, in addition to the information previously listed, the temporal relationship of symptoms to eating should be determined. On examination the gland should be palpated for stones, and an attempt should be made to massage the gland, obtain fluid

for culture, or identify ductal obstruction. In the pediatric patients, ultrasonography is the first-line imaging modality to assess salivary gland masses. If an abscess is identified, fine-needle aspiration may be performed to decompress the gland and to obtain fluid for culture. Radiographs may facilitate visualization of sialoliths, although many are radiolucent. CT scans will help to identify ductal stones, strictures, abscesses, and tumors. Sialography involves injecting contrast retrograde into the duct to detect pathology. It can provide useful information but is difficult to perform in children. Sialendoscopy is also difficult to perform in children but allows visualization of ductal anatomy and pathology. Treatment of sialadenitis includes antibiotics when indicated, aspiration or incision and drainage of the abscess, sialogogues, warm compresses, and hydration.

Lymphadenitis

Lymphadenitis is inflammation of the lymph nodes. Bacterial lymphadenitis is more commonly seen in children younger than 4 years of age. Submandibular lymph nodes are the most frequently affected and are seen in more than half of patients. Organisms causing bacterial adenitis include *S. aureus*, *S. pyogenes*, *S. agalactiae*, *B. henselae*, and *E. coli*. Cat scratch disease is caused by *B. henselae*, and inoculation usually occurs through a cat bite or scratch. Most cases are found in patients younger than 20 years of age. Viral lymphadenitis is most often seen when reactive lymphadenopathy occurs after a viral upper respiratory tract infection. Causative organisms include adenovirus, rhinovirus, coxsackievirus, and Epstein-Barr virus. Granulomatous diseases may be caused by organisms such as atypical mycobacteria, tuberculosis, actinomycosis, and sarcoidosis. Epstein-Barr virus is associated with infectious mononucleosis, which frequently affects adolescents. Patients classically present with the triad of lymphadenopathy, acute pharyngitis, and fever. Splenomegaly may occur, and patients should refrain from participation in contact sports and other activities to prevent splenic rupture.

Inflammatory Lesions

Noninfectious inflammatory pathology can cause lymphadenopathy in the head and neck region. Causes of noninfectious inflammatory disease include vasculitis, autoimmune disease, and drug side effects.

Kawasaki Disease

Kawasaki disease is a vasculitis of medium-sized vessels that typically affects patients younger than 5 years of age. Diagnosis of Kawasaki disease is made clinically with 5 days of fever plus 4 days of the following symptoms: cervical lymphadenopathy, conjunctival injection, an erythematous/edematous rash on the hands and feet, strawberry tongue/lip fissures, and a polymorphous rash. Without treatment, about 25% of children will also develop coronary artery aneurysms. Treatment consists of aspirin and gamma-globulin therapy, with the goal of decreasing inflammation, symptoms, and complications.

Sjögren Syndrome

Sjögren syndrome is an autoimmune disease targeting the salivary and lacrimal glands. The major symptoms are keratoconjunctivitis, sicca, and xerostomia. In children, the most common symptom at presentation is salivary gland enlargement. Diagnosis may be aided with laboratory tests, including an elevated erythrocyte sedimentation rate, positive antinuclear antibody, positive rheumatoid factor, positive SS-A and SS-B, and hypergammaglobulinemia. Treatment is mainly aimed at symptom alleviation.

Sarcoidosis

Sarcoidosis is a systemic inflammatory disease of unknown cause. Although sarcoidosis typically affects individuals in their twenties, it may be seen in any age group. Symptoms vary depending on which organs are affected by the disease. Cervical lymphadenopathy is the most common head and neck manifestation of sarcoidosis. Most patients require only symptomatic treatment. For more severe disease, corticosteroids or other medical therapies are used.

Juvenile Recurrent Parotitis

Juvenile recurrent parotitis or *recurrent parotitis of childhood* is an inflammatory disorder of the parotid gland. It is most commonly seen in children 3 to 6 years of age. Although its cause is unknown, the disorder is characterized by pain and swelling of one parotid gland and associated fever and malaise, with one to five recurrences per year. Although each episode tends to be unilateral, both parotid glands are usually involved. Episodes typically last less than 1 week and are self-limited. On physical examination, patients present with parotid swelling and pain. Purulent secretions may be expressed from the gland. Diagnosis is supported by sialiectasis on sialography.²⁸ Treatment is generally supportive, but ductal irrigation may reduce the number of recurrences.¹⁴

Drug-Induced Lymphadenopathy

Drug-induced lymphadenopathy can be caused by a variety of medications, including anticonvulsants, antithyroidals, isoniazid, hydralazine, allopurinol, and phenytoin. In most patients, adenopathy resolves after the causative drug is discontinued.

NEOPLASTIC LESIONS

Cervical Lymphadenopathy

Cervical lymphadenopathy most likely has an inflammatory or infectious cause. However, 1.5 in 10,000 children younger than 20 years of age will be diagnosed with cancer, and 5% of neoplasms in children manifest in the head and neck region.^{9,31,32} Although most neoplasms in children are benign, as many as 10% are malignant.¹ Cervical lymphadenopathy that does not respond to initial intervention must have a workup to rule out malignancy. A rule of thumb is that a lymph node larger than 2 cm for longer than 2 months should undergo a biopsy procedure unless an infectious cause has been documented.

Lymphoma

Lymphoma is the most common malignancy in children, followed by retinoblastoma, rhabdomyosarcoma, neuroblastoma, thyroid carcinoma, and melanoma.¹⁴ In diagnosing these lesions, invasive procedures and imaging may require sedation. An effort should be made to minimize ionizing radiation and the need for sedation. Multiple procedures or imaging studies should be combined whenever possible.

Improvements in the survival rates of children with cancer have been significant, with mortality decreasing by more than 50% from 1975 to 2010.^{33,34} Children with a cancer diagnosis should generally be evaluated and treated in pediatric cancer centers, because this has shown a survival benefit in multiple different malignancies.³³ In this setting pediatric plastic surgeons may be asked to aid with tumor diagnosis by performing open biopsy procedures and possibly tumor extirpation. Usually, however, plastic surgeons perform complex reconstruction after resection of the lesion. Reconstruction can be challenging, with large hard and soft tissue defects to recapitulate, often in irradiated tissues (Fig. 37-13).

Fig. 37-13 A, The preoperative appearance of an 18-year-old boy who underwent rhabdomyosarcoma excision and radiotherapy to the right side of the neck when he was a child. B, The outline highlights the area to be reconstructed. C, An extended preauricular incision made for adequate exposure of recipient vessels in the neck and to optimize the aesthetic appearance. D, A free anterolateral thigh flap used to restore facial volume. E, Postoperative appearance with improved facial symmetry at 4 months.

Lymphoproliferative Conditions and Histiocytoses

Lymphoma is not only the most common malignancy in children, it is also the most common pediatric head and neck cancer.^{14,35} Lymphomas represent a diverse group of neoplasms of the lymphoreticular system. They are classified primarily as either *Hodgkin lymphoma* (HL) or *non-Hodgkin lymphoma* (NHL).

Although not well understood, there appears to be an association between infection with the Epstein-Barr virus and multiple pediatric malignancies, including HL and NHL. Initially, patients with a history of Epstein-Barr virus were thought to have an increased epidemiologic risk of developing lymphoma.^{36,37} Subsequent studies have demonstrated high rates of Epstein-Barr virus positivity among tumor cells.³⁷ This is particularly true in the endemic form of Burkitt lymphoma.

Hodgkin Lymphoma

HL accounts for 6% of pediatric malignancies. It has a bimodal age distribution, which peaks in patients 15 to 40 years of age and in those older than 60 years of age. Clinically, it may be classified by age group: childhood (younger than 14 years of age), young adult (15 to 34 years), and older adult (55 to 74 years).³⁸ In industrialized nations, the incidence of HL is highest in adolescents 15 to 19 years of age, whereas in the developing world, the incidence is higher in childhood.³⁸ *Reed-Sternberg cells* are identified histologically as large, multilobular/multinucleated cells and are pathognomonic for HL.

Clinically, HL typically presents as an asymptomatic cervical or supraclavicular “rubbery” mass. Patients may complain of so-called “B symptoms” or constitutional symptoms, which include a fever higher than 38° C for 3 consecutive days, weight loss of 10% in the 6 months preceding presentation, and drenching night sweats. Patients may have been seen and treated previously for a presumed inflammatory or infectious cause.

Preoperative treatment includes a thorough history and physical examination. Standard laboratory tests include a complete blood cell count and metabolic panel, serum copper and serum ferritin levels, erythrocyte sedimentation rate, and C-reactive protein. Imaging may be performed and can include a chest radiograph, neck/chest CT, abdomen/pelvis CT or MRI, and a PET scan. Further intervention includes obtaining a bone marrow biopsy and CSF sampling.

Unlike solid tumors, staging for HL is based on the anatomic location of the disease. The Ann Arbor staging system with Cotswold modification is currently used to stage patients diagnosed with HL and to monitor their progress³⁹ (Table 37-2). Previously, surgical staging was performed with an exploratory laparotomy for lymph node biopsy or splenectomy. Current imaging techniques can provide information about abdominal lymphatic and extralymphatic involvement.

Treatment for HL is multimodal with chemotherapy and radiotherapy. Because of the high survival rates of this disease, it is particularly important to prevent the iatrogenic effects of therapy. Treatment protocols aimed at minimizing chemotherapy and radiation doses have been developed for this purpose.

The prognosis for children and adolescents with HL is excellent, with a disease-specific and overall survival rate of more than 90%.^{40,40a} Factors associated with a poorer prognosis include advanced stage, the presence of B symptoms, bulky disease or extranodal involvement, leukocytosis, an elevated erythrocyte sedimentation rate, anemia, and male sex.⁴⁰

Table 37-2 Cotswold Modification of the Ann Arbor Staging System

Stage	Area of Involvement
I	Single lymph node group
II	Multiple lymph node groups on the same side of the diaphragm
III	Multiple lymph node groups on both sides of the diaphragm
IV	Multiple extranodal sites or lymph nodes and extranodal disease
X	Bulk >10 cm
E	Extranodal extension or a single, isolated site of extranodal disease
A/B	B symptoms: weight loss >10%, fever, drenching night sweats

Non-Hodgkin Lymphoma

NHL is a diverse group of diseases of lymphoid origin that can arise from T cells, B cells, or natural killer cells. It accounts for approximately 7% of malignancies in patients younger than 20 years of age, and the incidence is highest in adolescents, similar to HL.⁴¹ NHL is divided into several subtypes based on cell of origin, including Burkitt lymphoma, diffuse large B-cell lymphoma, lymphoblastic T- or B-cell lymphoma, and anaplastic large-cell lymphoma. Other subtypes such as follicular lymphoma and marginal zone lymphoma exist but are significantly less common. Histologically, a “starry sky” appearance is seen because of the numerous macrophages that have consumed the apoptotic cells. Of all of the various subtypes of NHL, Burkitt lymphoma is the most common.

In contrast to HL, patients with NHL are more likely to present with diffuse, extranodal disease. Extranodal disease is most frequently seen in the liver, lungs, and bone marrow. In addition to a history and physical examination, patients should undergo the laboratory workup and imaging studies described for HL. The most consistently used staging system for NHL is the St. Jude (Murphy) staging system⁴² (Table 37-3).

Treatment for NHL in children is primarily nonsurgical and consists of various chemotherapy regimens. Radiotherapy, although used to treat adult NHL, is not frequently used in children.

The prognosis for NHL has significantly improved during the past 25 years, with an event-free survival rate of more than 80%, regardless of subtype. The survival rate with Burkitt lymphoma is even higher. The presence of bone marrow or CNS involvement is a poor prognostic sign.³⁴

Burkitt Lymphoma

Burkitt lymphoma has been classified into three distinct clinical forms: endemic, sporadic, and immunodeficiency associated. All of these forms are associated with a translocation of the *c-myc* oncogene on chromosome 8. Endemic Burkitt lymphoma is found primarily in Africa, where it accounts for up to 50% of all childhood cancer. Its incidence is approximately 8 in 100,000, with the highest incidence in children 4 to 7 years of age. Males are affected twice as frequently as females. Tumor location is the jaw in more than half of cases, with abdominal tumors also seen but less common. Ninety-five percent of cases are associated with the Epstein-Barr virus in tumor cells.⁴³ Sporadic Burkitt lymphoma is found in North America and Western Europe. Its incidence is 3 in 1,000,000, accounting for about 3% of pediatric lymphoma in the region. The highest incidence is in children 6 to 12 years of age, with males more frequently affected than females. Tumor location is most frequently the abdomen.⁴⁴ In sporadic Burkitt lymphoma, the Epstein-Barr virus is associated with only 15% of cases. Immunodeficiency-associated Burkitt lymphoma is less common than the other two forms and less relevant in the pediatric population. It is seen in patients with HIV infection.

Sarcomas

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common soft tissue sarcoma in children, representing 4.5% of all childhood malignancies.^{45,46} Of children affected, 35% present with a primary head and neck tumor. The orbit is the most common site involved in head and neck tumors, but multiple other sites throughout the region may also be affected. Rhabdomyosarcoma has a bimodal age distribution, with peaks at 2 to 6 years of age and 10 to 18 years of age. This is partly because there are two histologic subtypes: embryonal and alveolar. The embryonal subtype has a higher incidence in infants and is less common through childhood. Embryonal-subtype tumors are more frequently located in the head and neck region. In contrast, alveolar-subtype lesions have a higher incidence

Table 37-3 Staging System for Non-Hodgkin Lymphoma

Stage	Staging for Hodgkin Lymphoma	Staging for Non-Hodgkin Lymphoma
I	Only one lymph node region/structure involved Only a single extranodal site	Single tumor/nodal area involved, excluding the abdomen and mediastinum
II	Two or more lymph node regions/structures on the same side of the diaphragm, ± local, contiguous, extranodal spread	Single tumor with regional nodal involvement Two tumors/nodal areas ± regional nodal involvement on the same side of the diaphragm Primary gastrointestinal tumor grossly completely resected ± mesenteric nodal involvement
III	Lymph node regions or structures above and below the diaphragm are involved, ± spleen, ± extranodal site, or both	Two or more tumors/nodal areas on the opposite sides of the diaphragm All primary intrathoracic disease (mediastinal, thymic, pleural) Extensive primary intraabdominal disease Paraspinal or epidural tumors
IV	Disseminated involvement of extranodal sites	Bone marrow or central nervous system involvement

in older children and adolescents and more commonly affect the trunk and extremities. Most cases of rhabdomyosarcoma are sporadic but are associated with some familial syndromes, including Li-Fraumeni syndrome and neurofibromatosis.⁴⁵

Patients typically present with a firm, painless mass in the affected area. Although frequently asymptomatic, tumors, especially of the head and neck region, may exert a mass effect on surrounding structures and cause symptoms such as nasal obstruction, rhinorrhea, sinusitis, epistaxis, and cranial nerve palsy. A workup of these patients includes a history and physical examination, including a full cranial nerve examination. Laboratory studies should include a complete blood cell count, a complete metabolic panel, and a urinalysis. CT and MRI are the imaging modalities of choice for these tumors. A metastatic workup may be performed and includes a bone marrow aspirate, a CSF analysis, and a CT scan of the brain, lungs, and liver. A tumor biopsy and a sentinel lymph node biopsy should be performed to confirm the diagnosis and disease stage.

Rhabdomyosarcoma is staged before and after treatment. Pretreatment staging is a TNM staging system that considers the site and size of the primary tumor, the degree of tumor invasion, the nodal status, and the metastatic disease.^{45,47} After tumor excision, patients are assigned to clinical groups based on the completeness of tumor excision and metastasis^{45,47} (Box 37-3). The preoperative staging and postoperative clinical grouping allow patients to be risk stratified, which guides further treatment.

Treatment of patients with rhabdomyosarcoma is multimodal. After the diagnosis is confirmed with a biopsy sample, surgical resection should be attempted, with the goal of obtaining a circumferential margin of 0.5 cm around the tumor. Head and neck tumors do not require lymph node sampling of clinically or radiographically negative lymph nodes. In addition to surgical resection, patients receive adjuvant chemotherapy and some also receive radiotherapy.

The prognosis for patients with rhabdomyosarcoma is affected by a variety of factors. Overall, however, the 5-year survival rate is 67% for children younger than 15 years of age and 51% for those 15 to 19 years of age.³⁴

Box 37-3 Rhabdomyosarcoma Postresection Clinical Groups

- I. A: Localized tumor confined to the organ/muscle of origin, complete resection
B: Localized tumor infiltrating the outside site of origin but no lymph node involvement, complete resection
- II. A: Localized tumor with complete gross resection but residual microscopic disease
B: Regional disease in lymph nodes, complete resection
C: Regional disease in lymph nodes with complete gross resection but residual microscopic disease
- III. A: Localized tumor or regional disease with residual gross tumor after biopsy
B: Localized tumor or regional disease with residual gross tumor after resection
- IV. Distant metastases present

Box 37-4 Nonrhabdomyosarcoma Soft Tissue Sarcomas

- Fibrosarcoma
- Osteosarcoma
- Clear cell sarcoma
- Dermatofibrosarcoma protuberans
- Epithelioid sarcoma
- Malignant fibrous histiocytoma
- Hemangiopericytoma
- Malignant peripheral nerve sheath tumor
- Leiomyosarcoma
- Liposarcoma
- Chondrosarcoma
- Synovial sarcoma
- Desmoplastic small round cell tumor
- Alveolar soft part sarcoma
- Undifferentiated sarcoma

Nonrhabdomyosarcoma Soft Tissue Sarcomas

Nonrhabdomyosarcoma soft tissue sarcomas are a heterogeneous group of tumors that combined account for approximately 4% of pediatric malignancies⁴⁸ (Box 37-4). Although these tumors are rare, the most commonly encountered tumors in children are dermatofibrosarcoma protuberans, synovial sarcoma, malignant fibrous histiocytoma, malignant peripheral nerve sheath tumor, and fibrosarcoma.⁴⁹ In pediatric patients, those most commonly found in the head and neck region include malignant peripheral nerve sheath tumor, alveolar soft part sarcoma, and malignant fibrous histiocytoma. Most of these tumors occur sporadically, but some may be associated with an inherited syndrome. Children with Li-Fraumeni syndrome, neurofibromatosis type 1, and familial adenomatous polyposis are at significantly higher risk of developing a soft tissue sarcoma.

Fibrosarcomas

Fibrosarcomas are low-grade, locally aggressive tumors that arise from fibroblasts. They have a bimodal age distribution with two peaks: younger than 5 years of age and 10 to 15 years of age. These two peaks correspond to the two distinct forms of the disease.⁵⁰

Congenital/infantile fibrosarcoma occurs in the earlier of the two peaks and may present as a congenital lesion or in children younger than 2 years of age. Infantile fibrosarcoma is caused by a genetic translocation and is distinct from the childhood variant. Childhood fibrosarcoma occurs in the 5- to 10-year-old age group.⁵⁰ These lesions most commonly occur in the extremities but can also be found in the head and neck region. A workup includes a history and physical examination, with MRI for further tumor delineation. The treatment of choice is wide resection with generous surgical margins.⁵¹ Neoadjuvant chemotherapy may be used in some cases; adjuvant therapy is more controversial. The infantile form of the disease has a significantly better prognosis than the childhood form, with a 5-year survival rate of 84%, whereas the childhood form is more similar to adult fibrosarcoma, and the 5-year survival rate is 62%.⁵²

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans are low-grade, soft tissue sarcomas that most commonly occur on the trunk and extremities. An estimated 10% to 15% of these lesions occur in the head and neck region.⁵³ They may present as a congenital tumor or affect patients well into advanced age. About 6% to 20% of these diagnoses are in children.^{53,54} Although they have a low risk of metastasis, the lesions are tenacious with a high propensity to recur. On clinical examination, dermatofibrosarcoma protuberans have a highly variable appearance. Typically, they are asymptomatic, indurated nodular or plaque-like lesions with a firm consistency that are adherent to skin but not deeper structures.⁵⁵ Associated pigment changes may be present. The treatment of choice for these lesions is wide, local excision, with 2 to 4 cm margins to investing fascia or pericranium. Excision with smaller, more conservative margins has resulted in local recurrence of up to 60%.⁵⁵ Other risk factors for recurrence include histologic fibrosarcoma transformation, less than 1 mm from surgical margins, increased cellularity, a high mitotic rate, and age older than 50 years. Some advocate Mohs micrographic surgery for resection of this disease. Although this technique is controversial, advocates argue for its use, particularly in children in whom a 2 to 4 cm margin is quite large and for anatomic areas such as the head and neck. Adjuvant radiotherapy or imatinib may be used for persistently positive margins or residual microscopic disease (Fig. 37-14).

Fig. 37-14 Congenital dermatofibrosarcoma protuberans presenting as a firm reddish mass adjacent to but not overlying the anterior fontanelle. After confirmation, the adjacent scalp was expanded, and a wide resection and flap repair were carried out.

Synovial Sarcoma

Synovial sarcoma is a high-grade, spindle cell neoplasm that affects about 0.7 per million in the pediatric population.⁴⁰ It frequently occurs in close proximity to joints, joint capsules, tendon sheaths, and bursas. Most cases occur in the extremities, but it has also been reported in the head and neck. Patients with a synovial sarcoma usually present with slow-growing, painless tumors in the deeper soft tissues where they arise. Symptoms may arise from a mass effect on nearby structures. Imaging, including CT/MRI, is typically performed before a biopsy sample is obtained. Surgery with wide local excision is the mainstay of treatment for synovial sarcoma. Adjuvant radiotherapy may be used, but the use of chemotherapy is controversial. Overall survival rates of 70% at 5 years and 65% at 10 years have been reported in pediatric patients.⁵⁶ The prognosis is negatively affected by large tumor size (larger than 5 cm), tumors located in the lower extremity, and highly invasive tumors.⁵⁶

Carcinomas

Thyroid Carcinoma

Thyroid cancer in children is rare, accounting for 3% of pediatric cancer diagnoses.⁵⁷ However, it is the most common pediatric endocrine malignancy and accounts for approximately 5% of pediatric head and neck malignancies. Risk factors for developing thyroid cancer as a child include exposure to ionizing radiation, female sex, a personal or family history of thyroid disease, and iodine deficiency.⁵⁷⁻⁵⁹ There are several types of thyroid carcinoma, including papillary, follicular, and medullary. Papillary and follicular carcinoma originate in the follicular cells of the thyroid, and medullary carcinoma originates in the C cells. Although other subtypes exist, they are not typically found in children.

Papillary thyroid carcinoma is the most common type of thyroid cancer in both children and adults. In children it accounts for more than 90% of cases.¹⁴ Papillary thyroid carcinoma is frequently bilateral and multifocal; it usually metastasizes through the lymphatics, leading to regional disease. *Follicular thyroid carcinoma* is more often unifocal and metastasizes through hematogenous spread. Metastases are most commonly found in the lung and bones. *Medullary thyroid carcinoma* is often multifocal and bilateral. It is frequently associated with multiple endocrine neoplasia syndromes inherited in an autosomal dominant pattern.

Patients may or may not present with a thyroid nodule. The nodules are harder to palpate in children than in adults. When they are palpated, these nodules are significantly more likely to be malignant in children—approximately 25% of thyroid nodules in children are malignant compared with only 10% in adults.^{59,60} A thorough history, including details on previous radiation or benign thyroid disease and a physical examination, should be performed for all patients. Laboratory tests should include thyroid function studies. Imaging consists of initial thyroid ultrasonography and possible fine-needle aspiration biopsy. Further investigation with nuclear scintigraphy and CT may be performed.

Surgical excision is the first-line treatment of thyroid cancer in children. In cases of papillary and medullary carcinoma, a total thyroidectomy with parathyroid gland preservation is indicated with a low threshold to perform a selective neck dissection. For follicular carcinoma, a thyroid lobectomy may be performed. Radioactive iodine therapy is frequently used as adjuvant therapy in patients with papillary and follicular carcinoma, and adjuvant radiotherapy may be used in those with medullary carcinoma.

Although more than 65% of children have local lymph node metastases and 20% have distant metastases, the prognosis for children with thyroid cancer is good.⁶⁰ The average long-term survival rate for all subtypes is greater than 90%.^{61,62}

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma is a malignancy of the nasopharyngeal epithelium most often seen in adults. In children, it is usually found in adolescent males. The treatment is based on adult protocols, because this disease is rare in children. Surgical resection may be performed, although the disease may be unresectable as a result of the location and/or stage at presentation. Other therapy includes radiotherapy and chemotherapy (see Chapter 39 for further discussion of nasopharyngeal carcinoma).

Salivary Gland Carcinoma

There are three pairs of major salivary glands: the parotid, submandibular, and sublingual glands. In children salivary gland neoplasms account for less than 5% of these tumors overall. Salivary gland neoplasms are more likely to be malignant in children than in adults.⁶³ Benign neoplasms include pleiomorphic adenoma and Warthin tumor (papillary cystadenoma). Malignant lesions occur most frequently in the parotid gland (82%).⁶⁴ They include mucoepidermoid carcinoma, acinic cell carcinoma, adenocarcinoma, and adenoid cystic carcinoma, which collectively account for up to 90% of malignant salivary gland lesions in children.¹⁴

Pleiomorphic Adenoma

The most common benign neoplasm of the salivary glands is the *pleiomorphic adenoma*, which accounts for half of salivary gland tumors and more than 90% of benign salivary gland tumors in children.⁶⁴ Pleiomorphic adenomas present as slow-growing, painless, solid masses usually in the superficial parotid gland. They appear encapsulated on imaging but have microscopic extensions into the surrounding tissue, and thus superficial parotidectomy with facial nerve preservation is the treatment of choice. Warthin tumor, or papillary cystadenoma, is extremely rare in children.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is the most common malignant salivary gland lesion in children, representing more than half of malignant lesions in this population. It is primarily seen in adolescents. Most of these lesions in children are low-grade with a low rate of metastasis. Patients with mucoepidermoid carcinoma present with a slow-growing, painless, fixed mass in the parotid gland. With bulky disease, patients may have tenderness, dysphagia, trismus, and facial paralysis. Surgical excision is the treatment of choice. In parotid lesions this may be a superficial parotidectomy or total parotidectomy, possibly with neck dissection and/or radiation, depending on the tumor grade. The overall, 5-year survival rate is also affected by tumor grade. Low-grade lesions have more than a 92% 5-year survival rate, intermediate-grade lesions have a 62% to 92% 5-year survival rate, and high-grade lesions have a 0% to 43% 5-year survival rate.⁶⁵

Acinic Cell Carcinoma

Acinic cell carcinoma is the second most common salivary gland malignancy in children, making up 10% to 12% of these tumors. Like mucoepidermoid carcinoma, most of these lesions are low-grade and rarely metastasize. Presentation is also similar to mucoepidermoid carcinoma, with a painless, slow-growing mass, although these lesions are more likely to have associated symptoms of pain (30%) and facial paralysis (10%).⁶⁴ Parotid lesions are treated with parotidectomy (superficial or total) with facial nerve preservation. Adjuvant radiation is used with large tumors, positive margins, or recurrent lesions. Acinic cell carcinoma has a 10-year survival rate of more than 85%.⁶⁶

Melanoma

Melanoma is a cutaneous malignancy originating in the melanocytes—pigment-producing cells in the basal layer of the epidermis. It is relatively uncommon in children, accounting for 1% to 3% of pediatric malignancies.^{67,68} However, its incidence is increasing, and surgeons must keep this in mind when evaluating cutaneous lesions in children. The risk factors for melanoma include intermittent and intense ultraviolet light exposure, tendency to burn, freckly/fair skin, blue or green eyes, blonde or red hair, a family history of melanoma, and immunosuppression.⁶⁷ Other risk factors include skin conditions such as congenital melanocytic nevus, xeroderma pigmentosum, dysplastic nevus syndrome, atypical nevi, and acquired melanocytic nevi.⁶⁷

Pediatric melanoma can be categorized into four subgroups based on age⁶⁹:

1. Congenital (in utero to birth)
2. Infantile (birth to 1 year)
3. Childhood (1 year to puberty)
4. Adolescent (after puberty)

In congenital and infantile cases, melanoma may arise *de novo* in patients with a congenital melanocytic nevus or in utero from transplacental metastasis of maternal disease.⁵⁴ Giant congenital melanocytic nevi (diameter projected to be larger than 20 cm in adulthood) have been estimated to undergo malignant transformation in up to 12% of lesions.^{70,71} More recent data suggest that this is an overestimate, and that malignant transformation occurs in 0.7% to 2.9% of these lesions.⁷² Thirty percent of childhood melanomas are associated with a giant congenital melanocytic nevus. In adolescents the risk factors and profile of those affected are similar to those of adults, with the exception of a higher incidence in females.

In general, the presentation of children with melanoma is similar to that of adults with melanoma. Cutaneous lesions should be examined for signs of atypia. In children, as in adults, the trunk and extremities are the two sites most often involved (approximately 37%), followed by the head and neck region (29%).⁶⁸ Children are more likely to present with amelanotic lesions (Fig. 37-15). They may or may not present with palpable lymphadenopathy. The lesions may be difficult to distinguish clinically and histologically from a Spitz nevus, a benign lesion that appears so similar that they were once called *juvenile melanoma*.

A thorough history, including a family history, a physical examination, and a skin check are important in the diagnosis of melanoma. In part because it is so uncommon, many children have a delayed diagnosis or misdiagnosis (10%).⁷³ A high degree of suspicion and a low threshold to obtain a biopsy sample help to promptly diagnose lesions. A full-thickness biopsy for all suspicious lesions is essential to accurately assess thickness.

Surgical excision is the mainstay of treatment for melanoma. Excision margins are the same as those recommended for adult lesions by the National Comprehensive Cancer Network⁷⁴ (Table 37-4). A sentinel lymph node biopsy is performed in adults who have lesions greater than or equal to 1 mm and in those less than 1 mm with tumor ulceration, a high mitotic index, or other negative prognostic indicators. The role of a sentinel lymph node biopsy is not well described in children. However, it provides valuable information for disease staging and prognosis

and may direct further adjuvant therapy. The current recommendation is to perform a sentinel lymph node biopsy in children with the same indications as in adults.

The prognosis is affected by multiple factors. The stage at diagnosis, increasing thickness, a high mitotic index, ulceration or bleeding of the lesion, regional lymph node involvement, and systemic metastasis confer negative prognosis. In children, the 5-year melanoma-specific survival rate has been reported as 100% for in situ disease, 96.1% for localized disease, 77.2% for regional disease, and 57.3% for distant metastatic disease.^{68,73}

Fig. 37-15 A, Atypical amelanotic melanoma with spitzoid features in a 7-year-old girl. B, Surgical markings with a 1 cm margin. Methylene blue was injected for identification of the sentinel lymph node. C, The postoperative appearance after resection with negative surgical margins and a negative sentinel lymph node.

KEY POINTS

- Congenital and inflammatory causes account for most pediatric head and neck masses. In primary care settings, inflammatory causes are the most common reason for these masses, whereas congenital causes are more common in tertiary centers.
- Congenital lesions may not be diagnosed at birth. Diagnosis may be delayed until an inciting event—typically infection—causes the lesion to become more obvious.
- With improved prenatal ultrasonography, large, airway-compromising masses are increasingly detected, and an EXIT procedure may be planned at delivery.
- Cervical adenopathy is usually the result of infectious or inflammatory causes.
- Although malignant lesions of the head and neck are rare in children, if lymphadenopathy does not respond to initial treatment, the surgeon should consider malignancy in the differential diagnosis.
- Children treated for cancer have better outcomes for some malignancies when treated at comprehensive cancer centers.
- Pediatric plastic surgeons may be asked to obtain a biopsy sample of lesions of the head and neck, to excise lesions, and to perform reconstruction after lesion resection.
- Biopsies should be performed in a manner that does not compromise future reexcision or reconstruction.
- Surgery to excise lesions of the head and neck may require wide exposure and intraoperative nerve monitoring to adequately visualize and protect vital structures.

Facial Paralysis and Facial Reanimation

Jeffrey R. Marcus • Gregory H. Borschel • Ronald M. Zuker

Cross-Facial Nerve Grafting for Smile: Extended and Standard; Segmental Gracilis Muscle Transfer: Extended and Standard; Microsurgical Facial Paralysis Reconstruction.

he term *facial paralysis* describes a physical inability to activate the muscles of facial expression. It is a condition of great variability. Impairment of the facial neuromotor system is associated with a wide range of causes. Even patients affected by conditions with similar causes can present in a variable manner and require different management strategies. Common to all affected by facial paralysis is concern over its effects—both functional and psychosocial. Clinicians immediately understand the functional implications of facial paralysis, including the consequences of oral incompetence and an inability to protect and lubricate the cornea. However, what makes facial paralysis such a unique medical entity is the human perceptual linkage between physical expression and emotion. During effective social interaction, emotion is associated with expression, which an observer perceives and reciprocates. This response is vital to effective social interaction. In a fraction of a second, we process visual information from a person's face and infer sex, age, status, mood, and intentions. The outcome of this processing influences our interaction with the owner of the face.¹ A disconnect in the sequence of expression and perception will compromise the quality of the interaction. Observers in general instinctively and acutely perceive asymmetry and associate it with unattractiveness. A person with unilateral facial paralysis presents an image discordant with an observer's expectations, potentially leading to incorrect assumptions regarding mood, personality, and intelligence.^{2,3} In *complete bilateral facial paralysis* (as in a child with Moebius syndrome), the facial display is symmetrical but unresponsive, leading to difficulties in conveying the emotional components of interpersonal communication. Regardless of the etiologic factors in unilateral or bilateral facial paralysis, coping with a relative inability to interact socially in this way is one of the most difficult aspects for patients with such physical constraints.

In this chapter we will discuss the approach to pediatric patients with facial paralysis. A practical etiologic classification of facial paralysis is presented, with emphasis on specific conditions. We review the normal and abnormal anatomy and the initial evaluation, pretreatment assessment, operative planning, surgical procedure, postoperative care, outcome analysis, and complications associated with the surgery.

EMBRYOLOGY

Motor neurons that organize to form the facial motor nuclei are derived from neuroblasts in the basal plates of the medulla and later shift cephalad to lie within the pons. Special visceral efferent fibers innervate striated skeletal muscles derived from the branchial arches. The primordial facial nerve is discernible in the fifth week of life and is composed of special visceral efferent neurons. The extratemporal facial nerve begins dividing into fascicles in the seventh week. Selected fascicles pass superficial to the parotid bud, which develops rapidly and ultimately surrounds the facial nerve. Branching of the facial nerve in this area is thought to occur as a result of fascicular separation from growth of the parotid gland and by expansive growth of the face.^{4,5}

The relationship between the development of the facial nerve and the external ear is important because of the concomitant time sequence. The external ear develops from the auricular hillocks, which arise from the first and second branchial arches. The hillocks begin to fuse by the end of the sixth week. Malformations of the first and second branchial arches, including the external ear (such as microtia), are thought to arise as a consequence of events between the sixth and twelfth weeks. Because this is also the critical developmental period for the facial nerve, auricular disorders should prompt investigation of facial nerve function. Such is the case in assessing a child with *hemifacial microsomia*, in which facial nerve dysfunction may accompany a constellation of first and second arch anomalies, including hemimandibular hypoplasia and microtia (Fig. 38-1).

A typical branchial arch contains an artery, a cartilaginous bar, a muscular component, and a nerve.⁵ The facial nerve is considered to be the nerve of the second branchial arch (Fig. 38-2). Myoblasts from the second branchial arch migrate from the neck to the head and give rise to the muscles of facial expression, the stapedius and stylohyoid muscles, and the posterior belly of the digastric muscle. In the absence of nerve supply, muscles will begin a developmental sequence and demonstrate an early spontaneous and stimuable response.⁶ However, without direct innervation, the muscle fibers degenerate and are resorbed, leaving a fibrous and sinewy residue.^{7,8} There are no distinct muscular planes. This has significant surgical implications, because identification of appropriate dissection levels becomes very difficult.

FACIAL NERVE ANATOMY

Central Nervous System

The facial nerve nucleus is located within the pons. Lesions in or distal to the pons will affect the entire ipsilateral facial musculature. These are the coordinated movements that provide eye protection, oral competence, and facial expression. The spontaneity component of facial expression requires input from the frontal lobe. Thus a true smile has connections to both the facial nerve nucleus and the frontal lobe, although the precise pathways have not been delineated.

The facial nerve fibers exit the facial nerve motor nucleus and pass dorsally encircling the nucleus of the abducens nerve and emerge at the lateral aspect of the pons in the angle formed by the junction of the cerebellum and pons (the cerebellopontine angle).⁹ The nerve then enters the internal auditory canal, proceeds through an infratemporal course, and exits the skull at the

Fig. 38-1 This 4-year-old boy has hemifacial microsomia. Associated anomalies include left anotia, mandibular hypoplasia, and unilateral facial paralysis involving buccal-zygomatic branches. A surgical plan must be presented to address the relevant anomalies in a cohesive time sequence.

Fig. 38-2 The facial nerve is considered to be the nerve of the second branchial arch. It innervates the muscles of facial expression, the stapedius and stylohyoid muscles, and the posterior belly of the digastric muscle.

stylomastoid foramen. This infratemporal course of the facial nerve is the longest course of any nerve in the body through a bony canal (30 mm). It is divided into three segments: (1) labyrinthine (the narrowest site), (2) tympanic (horizontal), and (3) mastoid (vertical).^{4,10}

Extratemporal Course

The extratemporal course of the facial nerve is well characterized. Several key anatomic points merit discussion, along with associated references with which readers should be familiar. Baker and Conley^{11,12} and Davis¹³ described general variations of facial nerve anatomy. Classically, after initial branching to form the temporofacial and cervicofacial main branches, five terminal branches are designated: (1) temporal (frontal), (2) zygomatic, (3) buccal, (4) marginal mandibular, and (5) cervical. Significant crossover occurs among the zygomatic and buccal branches, causing variability of innervation to the central face. For this reason, traumatic injuries to distal branches (medial to the lateral canthus) in the cheek tend not to result in functional loss. This anatomic pattern is also relevant in reanimation of a paralyzed face, specifically with respect to innervation of the zygomaticus and levator muscles. Here, a specific distal branch can be sacrificed to provide a proximal source of contralateral (normal) innervation for grafting to the paralyzed side, without loss of innervation to the normal side. Such is not the case for the temporal, marginal mandibular, and cervical branches, which have little crossover, and transection of single branches can easily result in loss of function to the target musculature, such as the frontalis, the depressor labii inferioris, and the platysma muscles, respectively. Therefore considerable attention has been paid to the courses of these nerves in the context of rhytidectomy. Stuzin et al,¹⁴ Seckel,¹⁵ Dingman and Grabb,¹⁶ and Pitanguy and Ramos¹⁷ have published valuable articles on this subject. Branches of the facial nerve innervate target musculature on the deep surface consistently in all but three muscles: the levator anguli superioris, the buccinator, and the mentalis. These muscles are innervated on their superficial surface, a consequence of the deeper relative location of these muscles.

ETIOLOGIC CLASSIFICATION OF PEDIATRIC FACIAL PARALYSIS

Several authors have classified the extensive differential diagnosis of facial paralysis. May¹⁸⁻²⁰ noted more than 100 possible causes in a review of the medical literature between 1900 and 1996. In clinical practice, a systematic approach may be more useful rather than considering an inclusive list of specific diagnoses. Westin and Zuker²¹ proposed a classification system for facial paralysis intended to allow more general categorization and greater applicability to pediatric conditions. The major etiologic subheadings are indicated in Box 38-1. All presentations of facial paralysis may be appropriately assigned within this set of general categories, although the published classification system is far more detailed. Every case should be characterized not only by cause, but also by localization of findings (side-specificity and affected branches).

Pediatric cases are either congenital or acquired. The decisive factor is the likely causative event, rather than the age at presentation. Congenital conditions include any process or event occurring during prenatal development and are classified as syndromic or isolated nonsyndromic entities. Acquired conditions occur from the time of delivery through adulthood.

Congenital Conditions

Several diagnoses merit specific discussion. Unilateral facial paralysis present at birth may be the consequence of an obstetric injury; more often, it occurs as a developmental anomaly in isolated presentation or in conjunction with other physical findings.

*Nearly all specific causes may be classified within this general outline. Further side and branch specificity and extent (complete versus incomplete) provide a comprehensive classification.

Fig. 38-3 This child with Moebius syndrome has bilateral complete facial nerve palsy and incomplete abducens and hypoglossal nerve palsies.

Hemifacial microsomia describes a heterogeneous group of conditions affecting the first and second branchial arch derivatives. The facial nerve is considered the nerve of the second branchial arch; as such, it may be affected in cases of hemifacial microsomia or Goldenhar syndrome, a specific related variant. The extent and severity of facial nerve involvement and branch specificity vary in hemifacial microsomia.

Bilateral facial paralysis among children is rare. The most common congenital presentation of bilateral facial paralysis occurs in Moebius syndrome, which is a congenital syndromic condition characterized by expressionless facies that remains unchanged through the entire range of emotions. It is seen in association with palsies of the sixth, ninth, tenth, and twelfth cranial nerves, the most common of which is abducens (sixth cranial nerve) palsy (Fig. 38-3). Moebius syndrome is frequently associated with limb anomalies, including club foot, syndactyly, and Poland anomaly. The etiologic factors in Moebius syndrome are unknown; however, in selected groups, associations to autosomal dominant inheritance have been proposed.²¹⁻²⁶

Fig. 38-4 This child presented with a posterior fossa medulloblastoma and underwent resection. **A** and **B**, Two years after surgery, she continued to have an incomplete seventh cranial nerve palsy primarily affecting buccal-zygomatic branches. She underwent cross-face nerve grafting and a free gracilis transfer. **C**, The patient is shown 6 months after reanimation.

Acquired Conditions

In the pediatric population, congenital anomalies are most prevalent. Acquired facial paralyses occur, although with a different distribution than in adults. In children, traumatic injuries and tumors are most commonly seen. Blunt, traumatic cranial base injuries may result in bilateral paralysis. Penetrating injuries, on the other hand, are generally isolated injuries to the extratemporal facial nerve branches. Tumors may be benign or malignant, occurring in an intracranial or extracranial site. Acoustic neuroma is the most common tumor-related cause of facial paralysis in adults. In children, ependymoma and medulloblastoma are more often seen (Fig. 38-4).

PREOPERATIVE ASSESSMENT

Patient History

Based on information from a patient's history, the surgeon should do the following: (1) establish the likely cause, (2) characterize the anatomy of the pattern of branch involvement, (3) determine functional status with relation to corneal protection and oral competence, and (4) chart the course of events, including onset, progression, and duration of the condition. Each of these priorities is necessary for planning the intervention.

The cause is a key factor in determining treatment and expected outcomes. A child with unilateral congenital facial paralysis would not be expected to regain function over time; in addition, the lack of native facial musculature would preclude the ability to reinnervate via cross-face nerve grafting or neurotization alone. On the other hand, in posttraumatic (acquired) facial paralysis resulting from blunt head injury, observation may be the most appropriate initial recommendation.

Determining the pattern of branch involvement and the presence of specific functional deficits is necessary for potential surgical planning. The first concern is protection of the cornea. Children with congenital facial paralysis (including Moebius syndrome) rarely have a complete

lack of corneal protection necessitating specific surgical procedures, such as gold weight insertion. Older children with acquired facial paralysis are more likely to have insufficient protective ability, more akin to that seen in adults overall.

The time course of events is necessary to determine the need and/or timing for intervention, particularly in patients with acquired deficits. Here, the status of the existing muscle motor endplates comes into question. For example, in the case of tumor resection with subsequent paralysis despite no known facial nerve or nucleus injury, understanding the length of time that has elapsed since the procedure helps surgeons to provide a prognosis and initial recommendations. A paralytic state that has persisted beyond 6 months without improvement is unlikely to resolve without intervention. In adults, reinnervation of existing musculature can be a reasonable option if up to 18 months of reinnervation can be provided from the onset of paralysis. Beyond this, the motor endplates tend to become less amenable to restoration of neural input. In pediatric patients, the specific time window may be greater.

Physical Examination and Grading

An examination should establish the historical factors mentioned previously. A detailed facial nerve examination is performed, with specific emphasis on the status of the cornea and the branch pattern and the extent of facial nerve involvement. Assistance and input from a trained facial rehabilitation specialist are important contributions. The extent of involvement in particular should be documented to facilitate recovery analysis and outcome measurement. Numerous grading systems are available for documenting the facial nerve status. A grading scale should be sufficiently sensitive to measure the natural course of a disability, from the onset of paralysis to the various states of recovery, and to detect changes over time or after treatment. It should have a high degree of reproducibility. The most commonly used grading scales include the House-Brackmann Grading Scale (HBGS) and the Toronto Facial Nerve Grading System (TFGS).²⁷⁻³⁴ The Facial Nerve Disorders Committee of the American Academy of Otolaryngology–Head and Neck Surgery adopted the HBGS as the standard for grading facial nerve recovery. The TFGS and the recently introduced MoReSS (movement, rest, secondary defect, and subjective) system³⁵ have addressed concerns regarding sensitivity and reproducibility with the HBGS. The practical yet comprehensive nature of these scales makes them suitable primary instruments for facial nerve grading.

Electrophysiologic Studies

The primary purpose of electrophysiologic studies in managing facial paralysis is to assist in determining the prognosis for recovery. It has limited use in congenital facial paralysis, because recovery is not possible in this group. In acquired facial paralysis, however, electrophysiologic studies may indicate the possibility of recovery; for these patients, surgical intervention is deferred. Nerve conduction studies and electromyography can be performed to follow facial nerve recovery. They are more helpful in adults recovering from Bell's palsy or resection of an intracranial tumor.

NONSURGICAL AND SURGICAL TREATMENT

In pediatric patients, surgical rather than nonsurgical management tends to be considered more often because of the predominant causes and their associated (often poor) prognoses. However, nonsurgical modalities may be beneficial in some cases, particularly those with incomplete paralysis. The distinction between complete and incomplete paralysis is sometimes unclear; it is based

on the presence of appreciable movement in the regional distribution of any facial nerve branch. Therefore a patient can have a complete paralysis in the distribution of the frontal branch, but an incomplete paralysis in the branches of the lower face. In *incomplete facial paralysis*, a theoretical potential for improvement exists, because some degree of neural input has sustained muscle fibers. A facial rehabilitation specialist may offer beneficial strategies using a variety of techniques. In children with complete or near-complete facial paralysis in any branch distribution, surgical treatment is the primary consideration. Surgical treatments are typically classified as static or dynamic procedures. *Static procedures* are intended to counteract paralytic effects through repositioning of structures and aiding in improved symmetry in repose. *Dynamic procedures* are intended to restore position and movement.

Nonsurgical Treatment

In unilateral incomplete facial paralysis, both sides of the face show function, with a disparity in the degree of function between the sides. A facial rehabilitation specialist may provide therapy to strengthen the weaker side and dampen the stronger side through exercise and biofeedback. This requires the understanding and cooperation of the patient. This can be a limiting factor in younger patients and/or those with developmental disability. Another nonsurgical adjunct in the treatment of facial paralysis is botulinum toxin (Botox). Usually, this is considered for marginal mandibular branch paralysis in which the normal side is overactive and causes considerable distortion, particularly with laughing and crying when the mouth is open. In this situation, the normal side can be injected with Botox to balance activity in the lower lip. A good test of effectiveness is an injection of bupivacaine, which paralyzes the musculature for 4 hours. The patient can assess the effectiveness and symptom resolution and then determine whether Botox would be beneficial. Although Botox injections have to be repeated every 3 to 6 months, long-term repetition may not be necessary, because some degree of adaptation may occur. If requested, a permanent surgical solution can be carried out later.³⁶⁻³⁹

Surgical Treatment

Static and dynamic operative strategies have been described for each of the regional territories of the facial nerve. The choice of procedures and their sequence must be individualized. Prioritization of functional deficits will guide the surgical itinerary. The treatment of the paralytic eyelid is generally the first consideration. Children have considerable skin elasticity; thus eyelid incompetence is not frequently seen. It usually can be controlled by drops alone in congenital cases. However, some acquired cases need surgery in childhood when control of corneal exposure is problematic.

Static Procedures

Treatment of the paralyzed upper and lower eyelid is indicated when dysfunction limits a patient's ability to protect the cornea, creating a risk for corneal exposure and sequelae. One of the most common means to provide corneal protection is through insertion of a gold weight implant to the upper lid.⁴⁰⁻⁴¹ The weight loads the tarsus and facilitates closure by gravity. Some refer to this as a static treatment, because it applies a constant force on the lid. Various weights are available depending on the severity of the condition and size of the patient. Selection of the appropriate implant and exact placement are crucial. Eyelid spring insertion is another option, which conceptually is more dynamic. However, it is technically more challenging.

Although gold weight implantation alone usually improves corneal protection, attention should also be given to the lower eyelids. Exposure results from an inability to close the lids, which is caused not only by loss of upper lid movement, but also by a descent in the position of the lower lid (lower lid ptosis). *Paralytic ectropion* is the most advanced stage of lower lid malposition; however, even mild malpositioning (manifested by degrees of scleral show) can sufficiently impair closure even with a properly placed upper lid weight. In general, lower lid procedures should be delayed until the degree of lower lid laxity is known. Therefore lid tightening procedures are generally not performed in the early stages after denervation (such as after a tumor ablation). In selected cases of more long-standing paralysis, gold weight implantation and lower lid tightening can be performed while the patient is under the same anesthetic. If this is chosen, the gold weight should be implanted before the lower lid procedure is performed so that the surgeon can estimate the amount of lower lid tightening required.

In mild-to-moderate conditions of lower lid laxity, canthopexy or canthoplasty can provide adequate support and repositioning of the lower lid. In severe lower lid ptosis and/or ectropion, a static tendon sling may be required. The sling is positioned along the lid margin, well supported at the medial and lateral canthi.³⁶ Brow malposition usually is not a major concern in pediatric patients until they have matured; over time, ptosis and relative differences in motion may become more apparent. Endoscopic brow lifting can be valuable for younger patients with unilateral brow paralysis.⁴² Standard cosmetic endoscopic brow-lift techniques are readily adaptable. The results appear to be durable for at least 1 year, with an acceptable aesthetic outcome. Recently, we have been using the Endotine absorbable anchor (Coapt Systems) for pediatric and adult patients, with acceptable results. The contralateral (nonparalyzed) side needs to be considered. In adults, if the contralateral side is ptotic, a bilateral brow lift may be needed. If the contralateral side is not ptotic (which is most often the case in children) and its activity results in obvious asymmetry, a frontal branch neurectomy, either surgically or with Botox, may be considered.

Long-standing cases of facial paralysis can lead to a shift or collapse of the nasal ala, resulting in relative nasal obstruction. Obstruction is caused by a medial shift in the alar base and by loss of dynamic ability to dilate the external valve. The cartilaginous structural support of the ala, provided by lower lateral cartilage, is generally not compromised. Therefore static procedures for nasal obstruction are designed primarily to reposition the ala. The alar base may be undermined through an upper buccal sulcus incision. The ala is repositioned and secured to the periosteum, or it may be secured using a small bone anchor. A tendon graft can also be used to reposition the nasal ala in severe cases with symptomatic obstruction.

In the lower face, the two primary concerns are loss of the ability to smile and impairment of oral competence. A wide variety of restorative procedures have been described for this region. Static procedures include the use of tendon/fascia, dermis, and synthetic materials placed to suspend the oral commissure.⁴³ For otherwise healthy pediatric patients, we do not generally recommend static procedures for treating the lower face. These patients are most amenable to dynamic reconstruction using microneurovascular muscle transplantation. Static suspension of the commissure may improve oral competence and rest symmetry but does nothing to restore the smile. The functional loss of smile is often the most concerning aspect of the condition to parents and children. Given the well-documented, successful experience in the young age group with microneurovascular muscle transfer and the associated lifelong benefits, it is our strong position to avoid the use of static procedures for the primary management of pediatric patients. For similar reasons, we do not recommend the use of regional muscle transfers, such as temporalis or masseter muscle transfers, in this group.⁴⁴

Dynamic Procedures

As opposed to static suspensory procedures, dynamic reconstruction provides movement, baseline muscle stimulation resulting in muscle tone, or both. A *dynamic procedure* requires a stimulatory source (a nerve) and an effector (a muscle). In pediatric patients, we think every effort should be made when possible to provide a motor source and an effector that most closely reproduces the normal state to provide coordinated, emotion-associated expression. As noted previously, this rationale excludes the use of regional muscle transfers such as temporalis or masseter muscle.

Several types of dynamic procedures have been reported. Their indications for reanimation can be explained according to the timing (and the mechanism) of functional loss. The timing situations that are encountered are acute, intermediate, and long-term or chronic. Acute and intermediate functional loss includes situations in which a stimulatory source is lost, but native musculature (that is, the effector) retains the ability to accept reinnervation based on existing, viable motor endplates. An example of an acute loss is a penetrating injury to the facial nerve along its course. The indication for repair/reconstruction is largely evident at the time of presentation. An intermediate presentation may occur because of the time elapsed from injury to referral or because of an inability to immediately establish the indication for surgery by nature of the mechanism and unpredictable recovery. An example is the onset of paralysis after a brainstem level tumor surgery in which the facial nerve was observed to be uninjured. In such circumstances, time must be allowed to establish the likelihood and potential outcome of nerve recovery. In acute and intermediate presentations, the strategy for reinnervation is based on reestablishment of the stimulatory source. The means by which to accomplish this may differ in the two settings. Patients in the long-term or chronic group, which includes those with congenital paralysis, have no native muscle effector present or capable of receiving stimulatory input and generating a response in the form of tone or movement. In this group, both the stimulus and the effector must be provided; therein lies the basis of free functional muscle transfer.

Nerve-based Dynamic Reconstruction: Nerve Repair, Nerve Graft, and Nerve Transfer

Where the facial musculature is potentially functional, surgeons can try to preserve the function of the facial musculature with a nerve-based reconstruction. The first form of nerve-based reconstruction for facial paralysis is a direct nerve repair. This can be done at any segment of the intracranial or extracranial path of the facial nerve and is always worthwhile. It may not provide perfect facial nerve function, but it can provide tone and baseline activity that can be very helpful for function. If the outcome of a nerve-based reconstruction is not adequate, an additional reconstruction can be performed.

Similarly, the second form of nerve-based reconstruction is a nerve graft to a defect in the facial nerve that cannot be directly coapted. This is very worthwhile at any point in the course of the facial nerve for the same reasons as noted previously, even though the result may not be perfect. Fig. 38-5 shows a patient with a nerve graft reconstruction with an additional microsurgical reconstruction. It demonstrates the tone and baseline activity of the nerve graft and the spontaneous excursion provided by the secondary microsurgical reconstruction.

The third form of nerve-based reconstruction that is gaining popularity reserves the function of the effector musculature with a nerve transfer. Various motor nerves, such as the hypoglossal, have been used as nerve transfers in an attempt to preserve function of the facial musculature. We prefer the motor nerve to the masseter, which can be fairly easily found and is described later.

In a nerve transfer scenario described by Klebuc,⁴⁵ the masseter nerve is transferred to the buccal branch of the facial nerve with a direct microcoaptation or with a small sural nerve jump

Fig. 38-5 **A**, This 7-year-old girl is shown preoperatively at rest. She had a facial paralysis secondary to cholesteotoma surgery carried out at 11 months of age. The damaged facial nerve was replaced with a greater auricular nerve graft and provided tone, eye protection, but little commissure elevation. **B**, When smiling, she had minimal commissure movement. **C**, She is shown postoperatively at rest after having a cross-face nerve graft–segmental gracilis muscle transplant as a dynamic reconstruction. This procedure is described in detail later in the chapter. **D** and **E**, Postoperative views show her small smile and full smile.

graft (Fig. 38-6). This patient had a complete facial paralysis, because the intratemporal component of his facial nerve had been destroyed in an acid burn. A nerve-based reconstruction was performed. The lower face was reinnervated with a nerve transfer from the motor nerve to masseter. The upper face was reinnervated using a cross-face nerve graft that connected the normal temporal branches of the facial nerve on the left side through an end-to-side graft, which then coursed across the forehead. The distal end of the graft was coapted end to end to the involved upper component of the facial nerve. Reinnervation occurred fairly rapidly to the lower face; activity was seen in about 6 months. Tone for the upper face and active movement did not begin until a year after the nerve grafting. However, the reconstruction provided tone in the upper face on the involved side and active movement with commissure elevation and nasolabial crease formation on the involved side.

Fig. 38-6 A, This 10-year-old boy is shown preoperatively at rest. He had facial paralysis from an acid burn. B, His smile was asymmetrical, demonstrating an almost complete facial paralysis. C, Intraoperative view showing the motor nerve to the masseter in close proximity to the facial nerve in preparation for coaptation to the buccal branch of the facial nerve on the involved side. D, He is shown 2 years postoperatively at rest. Resting tone is improved. E, Smiling, he has a natural-appearing nasolabial crease from innate effector musculature.

One difficulty in using neurotization procedures intermediately is that the paralyzed branches at the time of surgery are “silent.” Their ability to respond to electrical stimulation of the facial nerve for the purpose of dissection/exploration diminishes significantly within days of injury. The *babysitter procedure* was developed in response to this problem.⁴⁶ It was originally described as a two-stage procedure in which movement is regained based on the babysitter. The hypoglossal is coapted end to end or end to side to the proximal extratemporal facial nerve. At the same setting, a cross-face nerve graft or grafts are coapted at the normal side, brought across to the paralyzed side, and left in proximity of the more distal branches, but they are not coapted. In the second stage, the distal branches are stimuable based on hypoglossal (babysitter) input; the appropriate branches are selected and coapted to the waiting cross-face grafts. This process addresses the “silent nerve” problem and allows selective grafting of the donor nerves at the second stage.

This concept is used in the second form of nerve transfer designed to preserve the intact facial musculature and was proposed by Marcus. In this scenario, the motor nerve to the masseter is coapted to the proximal part of the facial nerve—the part activating the lower face and the periorbital region. The masseter functions as a babysitter, coapted to the facial nerve in end-to-end fashion. Similar to Dr. Terzis' design,⁴⁶ simultaneously, two sural nerve grafts are coapted to selected normal side branches and brought across in proximity to distal branches but not coapted: one for the upper face and one for the lower face. Once facial movement based on the masseter transfer is demonstrated, the nerve is amenable to selective stimulation. In the second stage, the cross-face grafts are coapted end to end to selected distal branches of the paralyzed side. Distally, the facial nerve branches substantially; therefore the proximal connection of the masseter nerve is not disrupted, preserving the contribution of these fibers. With this approach, the facial musculature has strong innervations from the masseter (although little tone) and spontaneous, synchronous innervations with tone from the cross-face nerve grafts. Both of these nerve transfer techniques show great promise in the reconstruction of facial paralysis when the facial musculature is still able to be reinnervated.

Muscle-based Dynamic Reconstruction: Free Functional Muscle Transplantation

Functional muscle transplantation for facial reanimation has become the procedure of choice for longstanding or developmental pediatric facial paralysis. Techniques for microvascular facial reanimation have evolved considerably over the past 15 to 20 years. We will describe our own approach with this treatment. Many other variations are offered by other dedicated groups. Regardless of the approach, functional muscle transplantation for facial paralysis requires a source of neural input and an effector muscle. In unilateral facial paralysis, our approach is a two-stage sequence of procedures. In the first stage, neural input is established through a cross-face nerve graft from the contralateral (normal) side of the face. The second stage, free muscle transfer, is generally performed after 6 to 12 months to allow nerve growth through the graft.

Stage I: Cross-Face Nerve Graft We prefer to use the contralateral facial nerve for neural input, rather than direct neurotization or grafting to an ipsilateral cranial nerve (such as the hypoglossal). The advantage of the contralateral facial nerve is its potential to provide simultaneous, emotionally driven stimulus to both sides, allowing restoration of a spontaneous emotional smile. The surgeon identifies and uses the specific branch of the normal facial nerve that creates smile on the normal side, with the least amount of peripheral distracting movements. This branch should provide movement primarily to the zygomaticus major, the zygomaticus minor, and the levator labii. It should not significantly provide stimulation to the orbicularis oris or the nasalis. This is a crucial point and will be described in detail in the facial dissection section. Great care is taken to ensure sufficient facial nerve components to continue to innervate the normal side (see accompanying video entitled Cross-Facial Nerve Grafting for Smile: Extended and Standard).

The facial dissection begins with a preauricular incision and a submandibular extension on the normal side (Fig. 38-7, *A*). Dissection is carried anteriorly in the subcutaneous plane to the anterior border of the parotid. At this point, the dissection is carried deep, and the facial nerve branches exiting the parotid fascia are identified (Fig. 38-7, *B*). With the aid of the nerve stimulator, the specific branch to be used is selected. This is the specific branch that goes to the zygomaticus major, the zygomaticus minor, and the levator labii (Fig. 38-7, *C*). It should have minimal effect, if any, on the orbicularis oris. Additional branches that will innervate the facial musculature on the normal side are identified and preserved (Fig. 38-7, *D*). In this way, the surgeon can ensure that the division of the selected branch for cross-face nerve grafting will not weaken the normal side.

A tunnel is created from the site of the selected facial nerve through the subcutaneous fat into the upper lip. The tunnel courses across the sulcus in a preperiosteal plane to a site immediately overlying the maxillary canine root on the affected or paralyzed side. A small incision in the buccal sulcus is made to aid in the placement of the graft. The facial dissection is now complete. The sural nerve is harvested.

Fig. 38-7 **A**, A design for an extended rhytidectomy exposure on the normal side. The inferior extension of the incision, traveling in curvilinear fashion below the angle of the mandible, allows adequate exposure of the nerve. The same incision will be used on the contralateral, affected side in the second stage for free muscle transplantation. **B**, The facial nerve branches on the normal side are identified, and a facial nerve map is generated. The branch that will be used is identified as *use*. The branch that is not to be used is indicated as *no*. The branch that will continue to enervate the muscle supplied by the branch to be used is indicated as *leave*. **C**, The nerve branches are stimulated, and the specific branch that provides movement of the commissure consistent with a natural smile will be selected. This is the branch that will serve as the donor for sural nerve graft coaptation. The specific branches to the zygomaticus major and minor are identified with the aid of the nerve stimulator. It is helpful to use a nerve stimulator capable of generating sustained (tetanic) contractions to better differentiate muscle actions. This is the branch that will be divided and coapted to the cross-face nerve graft. **D**, Identification and preservation of another branch to the distal muscle targets that will be left to innervate these muscles after the selected branch is divided is imperative. This photo identifies the branch that will be left.

We prefer the sural nerve for cross-face nerve grafting. The entire nerve is not needed, and we prefer to use only the proximal part. The patient is placed supine with the hip flexed, abducted, and externally rotated, and the knee flexed at 90 degrees. A beanbag placed under the hip is helpful. Some centers place the patient in a prone or lateral decubitus position. The branch pattern of the sural nerve is somewhat variable, particularly in the lower third of the leg. The upper two thirds, traveling largely between the heads of the gastrocnemius, have fewer branches and a more suitable caliber; currently, we prefer this segment. A length of approximately 12 cm in a child older than 5 to 6 years of age can easily be harvested through a series of two or three stairstep incisions along the upper two thirds of the leg (Fig. 38-8, *A*). A 4 cm transverse incision is made approximately 4 cm distal to the popliteal fossa over the midportion of the proximal calf. This dissection is carried deep to the fascia, and very carefully the fascia is opened transversely. The sural nerve is identified between the two heads of the gastrocnemius muscle. Usually, it is quite superficial, but it may be buried between the heads of the muscle. It is dissected free and traced proximally to the popliteal fossa, where it is transected and brought out into the incision. At this point, a nerve stripper can be used to further dissect the nerve distally. The stripper is placed through the nerve and deep to the fascia and then gently advanced distally. It should clear about 12 cm of nerve. A second incision can be made in the midcalf, just above the distal end of the stripper. The distal portion of the nerve can be cut and the nerve removed for transplant (Fig. 38-8, *B*). The stripper is removed, and the incisions are closed.

Fig. 38-8 *A*, The sural nerve is harvested from the proximal leg through transverse posterior-calf incisions. The nerve can be initially located in the proximal midline of the calf deep to the fascia and between the two heads of the gastrocnemius muscles. *B*, The nerve stripper has been passed from proximal to distal, a second incision made, the distal end of the nerve graft divided, and the graft removed. The stripper remains in place.

Fig. 38-9 A, Sural nerve graft in the face. One end is noted beneath the cheek flap; this will be coapted to the selected branch of the facial nerve. The other end is located in the buccal sulcus; this will be banked and will later serve as the neural input for the segmental gracilis muscle transplant. B, The micronerve coaptation has been carried out between the cross-face nerve graft and the selected branch of the facial nerve on the normal side.

If a stripper is not used, the proximal portion of the nerve is dissected as far distally as possible through the upper transverse incision. A second incision is made usually about 5 cm distal to the original incision. The nerve is identified, and the dissection is carried farther distally to the last stairstep incision, where the nerve is again identified, dissected distally, transected, and removed.

The sural nerve is then brought through the tunnel in the face (Fig. 38-9, A). One end is identified with a hemoclip and secured to the periosteum in the buccal sulcus with a nylon suture at the level of the canine. This will be helpful in identifying the nerve graft when stage 2—the muscle transplant—is carried out. The intraoral incision is closed. The other end is carefully coapted to the selected branch of the facial nerve on the normal side. The cheek flap is reflected anteriorly, and the microscope is brought in. A precise nerve coaptation is carried out between the sural nerve and the selected branch of the facial nerve under high-power magnification (Fig. 38-9, B).

A cross-face nerve graft procedure sets the stage for a muscle transplant. At the muscle transplant (6 to 12 months later), the buccal sulcus incision is reopened, and the nerve graft is identified. The clinical examination of the patient before surgery will provide evidence of nerve regeneration by the presence of a Tinel's sign (irritated nerve) over the maxillary canine. If the suitability of the nerve graft as a donor is in question, it may be helpful to send a sample to pathology for an intraoperative analysis. This will ensure the fascicles are healthy, viable, and satisfactory for reinnervating the muscle.

Stage II: Free Muscle Transfer Several muscles have been used for functioning muscle transplantation to the face for facial paralysis. These include the latissimus dorsi, pectoralis minor, extensor carpi radialis brevis, rectus abdominis, and gastrocnemius. However, we have found the gracilis to be the most useful. It has a consistent anatomy, can be harvested simultaneously with facial dissection, can be reduced in size to prevent bulk problems, has no functional loss when harvested, and leaves a relatively inconspicuous scar. The procedure is done with two teams (see accompanying video entitled Segmental Gracilis Muscle Transfer: Extended and Standard). Through a preauricular incision with a submandibular extension, a subcutaneous dissection plane is created. This extends anteriorly to the oral commissure and into the upper lip. Superiorly it

Fig. 38-10 **A**, A series of sutures is placed along the commissure and the upper lip. The placement of these sutures must be accurate to ensure proper creation of the nasolabial fold consistent with a natural smile. The sutures are placed in the sinewy material (which is representative of absent or atrophied facial musculature), with care to prevent inversion or eversion of the lip. **B**, The facial vessels are dissected. When divided, they can be transposed distally for microvascular anastomoses on the surface of the masseter muscle. **C**, The facial dissection in preparation for the muscle transplant is complete. The required length of muscle is the distance between the oral commissure (*short arrow*) and the root of the helix (*long arrow*); 1 cm is added to each end for suturing.

courses to the malar prominence and up over the temporalis fascia. Anchoring sutures for the muscle are placed in the oral commissure and upper lip. If the patient has a static droop of the oral commissure, then a suture is placed in the lateral part of the lower lip to provide support. One suture is placed in the oral commissure and, generally, two in the upper lip. The use of heavy (size 1 or 2) absorbable sutures helps to prevent the suture pulling through the muscle. With traction on these sutures, a well-defined nasolabial crease is created (Fig. 38-10, *A* through *C*). Just as the selection of the appropriate facial nerve branch is critical to the cross-face nerve graft, accurate placement of sutures is equally essential at this stage of the muscle transfer. The crease should be created at the same distance from the commissure as on the normal side. In the preoperative evaluation, the location of the crease and the vector of movement of the muscle are studied. The muscle is placed along the same vector seen on the normal side when the patient smiles. In cases of acquired paralysis, the surgeon visualizes the residual nonfunctioning orbicularis oris muscle and the insertion of the zygomaticus major and minor. This leads the surgeon to the proper plane for precise suture placement. If the sutures are placed too superficially, the lip will evert. If they are placed too deep, the lip will invert. Sutures are not necessary in the lower lip if little or no static droop is present in the oral commissure. They can be placed solely in the oral commissure and in the upper lip. In cases of congenital facial paralysis in which no native muscle is available to guide the surgeon, the sutures are placed in the sinewy material at the oral commissure and in the upper lip. This plane is difficult to identify, but the location of the facial artery is a very useful guide for appropriate suture placement.

The facial vessels are generally most suitable for revascularization of the muscle. The facial vein courses vertically upward just anterior to the anterior border of the masseter muscle. It is transected distally (superiorly) and reflected posteriorly for microvascular anastomoses. The facial artery courses anterior to the facial vein and toward the oral commissure. It is dissected to the commissure, transected, and reflected posteriorly. In this manner, the microvascular anastomoses are carried out above the surface of the masseter muscle, where visualization is straightforward (see Fig. 38-10, *C*).

Excess bulk is one of the most common problems after muscle transplantation to the face. It causes a facial asymmetry at rest but can be minimized in a number of ways. First, some of the excess subcutaneous fat in the cheek flap can be removed. The fat is removed in the area that will overlie the muscle transplant. Care is taken not to remove too much fat, because adherence to the dermis of the muscle will cause dimpling and distortion. Thus only the deep fat component is removed for contour purposes. We have found removal of part or all of the buccal fat pad to be extremely helpful in reducing bulkiness and excessive fullness in the cheek. This can be accomplished by spreading the muscle in the preauricular and temporal area at the time of transplantation so that it is not as thick as it might be just below and posterior to the malar prominence. Perhaps the most important factors are that the gracilis muscle can be longitudinally divided, and only 33% to 50% of the circumference of the muscle needs to be used, as described in the following discussion.

After the plane of dissection in the cheek has been prepared, the required length of muscle is determined. This is the distance from the oral commissure to the root of the helix when the oral commissure is positioned at the same level as the unaffected side. With slight traction on the sutures, the surgeon can position the oral commissure appropriately and then measure the distance from the commissure to the root of the helix. This is the functioning length of muscle that will be necessary. Generally, we harvest one additional centimeter on either end to accommodate suturing. Thus the functioning length plus 2 cm is the length of the gracilis muscle that will be required for reconstruction.

Muscle Elevation An upper medial thigh incision is made in a longitudinal fashion. A line is first drawn from the origin of the gracilis to its insertion on the tibia. The actual incision will lie 1 cm posterior to this line so that it will be less visible when viewed from an anterior perspective. The incision measures approximately 10 cm and is positioned such that the pedicle will lie centrally along the incision (Fig. 38-11). The dissection is carried through the subcutaneous fat to and through the fascia overlying the gracilis. A myocutaneous perforator coming from the gracilis muscle belly is often seen. This can aid the surgeon in identifying the pedicle, which should lie at the same longitudinal level as the perforator. The pedicle is identified and dissected to its origin. The vessels course at a 90-degree angle from the muscle, and the nerve courses at a 45-degree angle toward its takeoff from the obturator nerve just distal to the obturator foramen. The muscle is dissected circumferentially, and the neurovascular pedicle is dissected back to its origins. The muscle is inspected for size reduction. Generally, the pedicle comes in on the deep surface of the anterior part of the muscle. Only 33% to 50% of the circumference of the muscle is required, but this will vary from patient to patient, depending on the size of the muscle (Fig. 38-12, *A*). Occasionally, the pedicle comes into the central part of the muscle. In this situation, segments from both the posterior part and the anterior part could be removed to provide the appropriate bulk reduction. The segment to be harvested is then marked. Generally, the pedicle is placed in the midportion of the muscle, but sometimes it can be altered to accommodate the position of the motor nerve and reduce the time of reinnervation.

In a unilateral facial paralysis situation, the pedicle should be closer to the proximal part of the muscle. This is the part that will be placed at the commissure and upper lip. Thus the motor nerve to the gracilis will course from the cheek into the upper lip through a tunnel for neural coaptation in the upper buccal sulcus. The muscle is cut to the appropriate length (Fig. 38-12, *B* and *C*). Mattress sutures are placed along the edge of the muscle that will be inserted to the oral commissure and upper lip. These mattress sutures are placed close to the edge of the muscle and throughout its length. They will be used to anchor the muscle with the sutures that have been

Fig. 38-11 The incision for the segmental gracilis harvest is positioned so that the pedicle will lie at about the midpoint of the incision. This allows the surgeon flexibility in designing the muscle flap with appropriate length on either side of the pedicle.

Fig. 38-12 A, The gracilis muscle may be split longitudinally to provide an innervated segment of suitable dimensions while preventing unnecessary bulk. B, The length of muscle needed to maintain the rest position of the commissure even with the normal side is determined. The length of muscle needed on either side of the pedicle is measured to place the pedicle at the appropriate position for anastomosis to the donor vessels. C, The muscle, ready for insertion into the face, is stimulated with a nerve stimulator.

placed in the oral commissure and upper lip. They will prevent sliding of these sutures through the muscle and malpositioning of the muscle. Should this occur, it is almost impossible to effectively correct.

Muscle Transplantation The muscle is transplanted to the face. The anchoring sutures are secured behind the mattress sutures. An additional bite into the tissues of the oral commissure and upper lip is placed, and the suture is placed once again behind the adjacent mattress suture (Fig. 38-13, A). Next, the muscle is slipped into position and secured. In this way, the muscle is not only appropriately positioned to create a natural nasolabial crease, but also is secure in this position, preventing suture pull-through. The motor nerve to the gracilis muscle transplant is placed through the previously created tunnel into the upper lip. Adequate length should be available for a tension-free nerve repair. The muscle is stretched temporarily to facilitate the microvascular anastomoses. Great care is taken not to kink the vessels of the pedicle or twist the facial artery or facial vein. Typically, the facial vein is repaired first and the facial artery second. After this, the motor nerve is repaired. After the nerve repair is completed, the vessels are inspected for patency. The entire muscle should be well vascularized.

Fig. 38-13 **A**, The segmental gracilis muscle is carefully inserted into the facial pocket. **B**, Unilateral facial paralysis. Repair of the nerve to the gracilis muscle and a cross-face nerve graft in the buccal sulcus, which is done using an operating microscope.

Fig. 38-14 The muscle is secured to the oral commissure and upper lip. The origin of the muscle is inset along the temporal fascia after the vascular anastomoses have been completed. Ideally, the tendinous origin will be available to secure the muscle at this inset.

The head is turned, the operating microscope shifted, and appropriate exposure established for the nerve coaptation in the upper buccal sulcus (Fig. 38-13, *B*). The motor nerve to the gracilis and the sural nerve graft are generally an excellent size match. After the epineural nerve repair under no tension, the buccal sulcus incision is closed.

The next important step is to secure the origin of the muscle. The muscle is gently stretched to the temporal fascia. It should course just below the malar prominence to prevent excess bulk in this region. It is spread over the temporal fascia and to the area just below the anterior helical margin in front of the tragus. The muscle is secured with mattress sutures to the temporal fascia using heavy 1 suture. The amount of tension should allow hardly any movement at the oral commissure (Fig. 38-14). The oral commissure should be in a neutral position to the opposite side to prevent excess tension on the muscle and distortion at rest. This will maximize the muscle's excursion with contraction. A silicone drain exits through a stab wound behind the ear. The cheek flap is repositioned without tension on the overlying muscle transplant.

Bilateral Facial Paralysis

The approach is altered when an ipsilateral facial nerve and contralateral facial nerve are available. This is most frequently encountered in Moebius syndrome; it is also seen in patients who have had brainstem tumors removed and have a residual bilateral seventh nerve paralysis. We initially used the hypoglossal nerve in such situations to innervate muscle transplants but have not found it to be satisfactory. Power is not sufficient to effect adequate excursion, and the tongue may have an unacceptable motor dysfunction. Children with Moebius syndrome often have other speech difficulties, and reduction in tongue mobility could further impair speech. Although end-to-side repairs to the hypoglossal nerve have been described, they do not provide sufficient innervation to the muscle for effective contraction. We prefer to innervate the muscle in such cases with the motor nerve to the masseter muscle.

The motor nerve to the masseter muscle (that is, the masseteric nerve) provides a robust source of donor motor axons for use in rehabilitating facial paralysis. It can be used as a nerve transfer directly into an acutely injured facial nerve,^{45,47} as described previously; it can also be used to innervate a muscle transplant, such as the gracilis muscle.

Surgeons may wish to use the following landmarks as a guide to facilitate the dissection of the motor nerve to the masseter, as described by Borschel et al.⁴⁸ First, the masseteric nerve is located 3 cm medial to the tragus and 1 cm inferior (3 and 1) to the zygomatic arch.

The masseter muscle consists of three lobes: superficial, intermediate, and deep. The motor nerve to the masseter travels inferomedially within the space between the intermediate and deep lobes.⁴⁹ Electrocautery is used to make a transverse incision at the 3-and-1 point in cases of complete facial paralysis. In cases in which some facial nerve functions remain intact, this initial portion of the dissection is carried out using blunt dissection. On entering the fascia, the masseter muscle is readily identified, and dissection proceeds with blunt scissors dissection and placement of Ragnell retractors. Every time the scissors are opened to dissect, the Ragnell retractors are replaced, in sequence, to the level of the deep lobe of the masseter muscle. Because it can sometimes be difficult to know when the deep lobe has been reached, probing the masseter muscle with an electrical stimulator/nerve locator (such as a battery-powered stimulator made by Medtronic) is quite useful. Masseter muscle activity is usually visualized using these maneuvers, leading the surgeon to the masseteric nerve (Fig. 38-15). Once identified, the masseteric nerve is dissected from its bed. Usually, a region of about 1 cm contains few branches. The nerve is transected and delivered out of the masseter muscle for coaptation.⁴⁸

Fig. 38-15 The approach to the motor nerve (arrow) to the masseter muscle.

The motor nerve to the masseter muscle generally has one or two large fascicles and provides excellent power to the transplanted muscle.^{47,50} When innervation is derived through the masseteric nerve (ipsilateral), the motor nerve to the gracilis may be shortened—an advantage for quicker and more effective reinnervation of the muscle. The nerve is coapted under high magnification. The nerve repair is completed before the muscle origin is secured, because it will lie beneath the final resting position of the transplanted gracilis muscle. The muscle is appropriately positioned. The wound is thoroughly irrigated and the cheek flap closed again over a silicone drain exiting through a postauricular stab wound.

POSTOPERATIVE CARE

An optimal environment for muscle revascularization is critical. Thus adequate fluid resuscitation, appropriate pain control, and protection of the operative site are essential. Patients are generally maintained on bed rest for the first day and then are gradually mobilized. Parents are instructed to avoid any significant contact with the operated site for 6 weeks. In our practice, perioperative antibiotics are given, but anticoagulants are not. Patients are instructed to not consume caffeine for 6 weeks to minimize the chance of vasoconstriction. When the motor nerve to the masseter

Fig. 38-16 Unilateral facial paralysis. A and B, This patient is shown preoperatively at rest and smiling. C and D, Approximately 5 years postoperatively, she is shown at rest and smiling.

is used (or in rare cases the ipsilateral facial nerve), innervations occurs in about 8 to 10 weeks, because the distance between the nerve coaptation and the muscle is minimized. When a cross-face nerve graft is used, the innervation may take up to 5 to 6 months.

Rehabilitation can be very helpful to improve the muscle excursion and symmetry of smile. Once the muscle has been reinnervated, a series of fairly simple exercises can be initiated. This can strengthen the transplanted muscle and improve excursion. With the use of biofeedback, symmetry of movement can be improved. This is done by performing the exercises in front of a mirror, where the amount of movement and the extent of excursion can be assessed by the patient. This should be done two to three times a day for 4 to 5 minutes. The patient will gain an understanding of what needs to be done with his or her newly transplanted muscle to achieve the symmetry of movement and the spontaneity desired. In unilateral facial paralysis treated with an appropriate cross-face nerve graft, spontaneity is not a problem; however, the extent of excursion may be problematic. Strengthening exercises can be of considerable benefit (Fig. 38-16). When the motor nerve to the masseter muscle has been used, complete spontaneity may not be obtained. However, a degree of spontaneity is possible with exercises performed in front of a mirror using biofeedback. This rather simple rehabilitation process should be carried out for about 6 months (Fig. 38-17).

Fig. 38-17 Moebius syndrome with bilateral facial paralysis. **A** and **B**, This patient is shown preoperatively at rest and smiling. **C** and **D**, Twelve months postoperatively, he is shown at rest and smiling.

RESULTS

The results of muscle transplantation for facial paralysis can be quite dramatic. However, to date, we are not able to perfectly replicate “normal” appearance and function. The muscle insertion can be placed close to the oral commissure and will achieve reasonable symmetry, but the nasolabial crease is very difficult to create in its superior portion (Fig. 38-18). Some patients show the lower teeth on the unaffected side when they smile. This is very difficult to duplicate with a single-vector reconstruction. Commissure excursion has improved significantly over the years as a result of optimizing muscle excursion with better, long-lasting fixation, appropriate tension, and increased fiber length. It is also improved as a result of greater motor input with the use of larger segments of the facial nerve from either the ipsilateral side or the contralateral side. We think that the use of a short-nerve graft with no branching has been helpful in providing additional input into the transplanted muscle. Nevertheless, muscle excursion often does not match the unaffected side and remains a problem, particularly with cross-face nerve graft–muscle transplantation combinations in older patients.

Symmetry is a concern in bilateral cases. Despite considerable effort directed at creating symmetrical insertions and symmetrical vectors, the result is not always perfect (Fig. 38-19). However, an excellent smile can be restored in most bilateral cases, particularly in patients who had no movement previously. The excursion that can be created with the motor nerve to the masseter is impressive. It approaches the normal excursion of the oral commissure on the unaffected side.

COMPLICATIONS

The complications of muscle transplantation to the face for facial paralysis can be described as *early* or *late*. The early complications are bleeding and infection. Even with careful hemostasis, hematomas can develop. This is particularly true on emergence from anesthesia, with increased blood pressure. Although we generally give perioperative antibiotics to prevent infections, they can occur. We found that thorough irrigation at several points during the facial dissection can be effective in reducing the incidence of infection. Abscess formation is very troublesome; it often occurs directly beneath the muscle and surrounding the vascular repairs. An open approach to abscess evacuation is necessary. We have found that the muscle remains viable, and the vascular repairs are relatively resilient. Muscle function can be restored even after significant abscess evacuation.

Late complications are most concerning and very difficult to correct. The most common is excess bulk at the site of the muscle transplant. Prevention of this complication is ideal. Treatment involves an open approach with removal of some of the subcutaneous fat and some of the muscle bulk in a tangential fashion. A second complication is disruption of the muscle insertion from the oral commissure and upper lip. This is an extremely troublesome complication and very difficult to correct. It is sometimes possible through an open approach to release the muscle from the surrounding scar tissue and to reposition it to the oral commissure and upper lip. However, great care is required to prevent excess tension and distortion of the lip. The scar tissue should be released and the muscle stretched to its original length. Successful repositioning is not always possible. A third complication involves excessive initial tightening of the muscle and resultant pulling of the oral commissure at rest. This can be improved by releasing the origin of the muscle in the preauricular region, allowing it to slide anteriorly. The muscle should be freed very carefully on its undersurface, where the motor nerve is located.

Another complication that is difficult to correct is inadequate movement. This may be the result of poor neural input or reduced viability of the muscle; however, the actual cause is often obscure. Occasionally, muscle strengthening exercises and rehabilitation are helpful in gaining

Fig. 38-18 Facial paralysis. **A**, This patient is shown postoperatively at rest. **B**, He is smiling 18 months postoperatively. He has incomplete formation of the upper component of this nasolabial crease.

Fig. 38-19 Bilateral facial paralysis of Moebius syndrome. **A-C**, This patient is shown preoperatively at rest, with maximal facial animation, and with maximal eye closure. **D-F**, She is shown postoperatively at rest, with a small smile (with fairly symmetrical nasolabial crease formation), and with a full smile (with asymmetrical nasolabial crease formation).

further excursion. We have also seen success with the use of electrical stimulation therapy. We have observed an increase in electrical activity and power over the course of 2 to 3 months of therapy. Electrical stimulation has been discouraged in the past in facial paralysis patients. However, the criticisms have focused primarily in adult Bell's palsy patients. In this group, stimulation of the native facial nerve can exacerbate synkinesis. In free muscle transplant patients, synkinesis is not a problem, because stimulation of the nerve graft is only directed to the transplanted muscle. If this is ineffective, the only option for improvement is to repeat the muscle transplant. Surgeons may wish to use a more powerful nerve. If the first reconstruction involved a cross-face nerve graft, a second muscle transplant might do better with innervation through the very powerful motor nerve to the masseter muscle.

CONCLUSION

Muscle transplantation for facial paralysis has provided an excellent means of dynamic restoration of facial animation. For near-normal spontaneity, the contralateral facial nerve can be used in a cross-face nerve graft. Great care is needed to select the appropriate branch. For a muscle transplant, we prefer the gracilis muscle. Accurate muscle placement and muscle fixation are necessary for the procedure to be successful. It is imperative to reduce bulk using only a fraction of the transplanted muscle and to remove the overlying fat and the buccal fat pad. Last, the muscle must be under the appropriate tension so that it barely moves the oral commissure and upper lip. In general, for unilateral facial paralysis, a two-stage approach is used. An initial cross-face sural nerve graft is carried out; 6 to 12 months later a free muscle transfer is performed. A key technical factor is the selection of the appropriate branch of the contralateral facial nerve in the first stage. In patients in whom neither the ipsilateral nor the contralateral seventh nerve is available, the use of the motor nerve to the masseter muscle to innervate the transplant has proved most effective.

KEY POINTS

- Facial paralysis can impose a major psychosocial barrier. A disconnect in the sequence of expression and perception compromises the quality of the interaction.
- Facial paralysis reconstruction can be either static or dynamic. Because of skin elasticity, the eyelids only rarely need surgery in children. In older adolescents and adults, a canthoplasty may be required. However, the lower face in children does best with a dynamic reconstruction rather than static sling support.
- The most critical aspect in a cross-face nerve graft procedure is the selection of the correct branch of the facial nerve on the normal side. Another branch needs to remain intact to innervate the musculature of the normal side. Harnessing sufficient axonal input is essential for adequate and effective muscle function.

- The most critical points in a muscle transplant procedure are (1) to correctly place the anchoring sutures in the commissure and upper lip, (2) to secure the muscle so it does not slip away from its insertion site, (3) to prevent excess bulk by using only 50% or less of the gracilis muscle circumference—removing the buccal fat pad and some subcutaneous fat in the area under which the muscle will lie—and (4) to use an effective motor such as the motor nerve to the masseter muscle.
- Late complications include excess bulk, muscle malposition, muscle tightness with distortion, and inadequate movement. These are extremely difficult if not impossible to correct secondarily. Thus surgeons should be aware of them and try to prevent them at the muscle transplantation procedure.
- Facial paralysis reconstruction in children can be extremely rewarding. However, each stage is fraught with potential pitfalls and complications that may not be correctable. Great care in patient selection and attention to detail in surgical execution are advised.

Pediatric Cranial Base Masses

Erin M. Rada • George Jallo • Amir H. Dorafshar

he cranial base is composed of the paired frontal, paired temporal, ethmoid, sphenoid, and occipital bones and forms the floor of the cranial cavity. It also separates the cranial cavity from the facial structures, including the sinuses and nasal and oral cavities. Cranial base lesions are relatively uncommon in children, and the lesions that do occur are more likely benign than those in adults. A greater percentage of benign lesions and increased rates of complete tumor resection resulting from defined tissue planes in children portend a better prognosis than in the adult population.¹ However, there are specific challenges when one is diagnosing and treating these lesions in children. The ability to surgically approach skull base lesions has long been one obstacle to their treatment; this difficulty is compounded by the small size of the pediatric cranium. The differing anatomic proportions and the presence of growth centers in the developing craniofacial skeleton pose additional hurdles in planning adequate exposure for resection.

PRESENTATION

Cranial base lesions, whether in children or adults, may be asymptomatic or can present with various symptoms, depending on the size and location of the tumor. Common complaints include vague symptoms such as headache, confusion, and nausea and vomiting. Symptoms may also be indicative of tumor location, including specific cranial nerve palsy, epistaxis, anosmia, difficulty breathing, hearing loss, tinnitus, vertigo, nausea, diplopia, and proptosis. Especially in younger children, it may be difficult to elicit specific symptoms before a lesion is sufficiently large to produce symptoms resulting from mass effect.

DIAGNOSIS

Patients may be seen by a variety of specialists before a definitive diagnosis is reached; this may include plastic surgeons, neurosurgeons, and otolaryngologists, based on the perceived issue and chief complaint. Skull base tumors should be considered part of the differential diagnosis, since they may present with a variety of seemingly unrelated symptoms. A thorough history and physical examination are essential to diagnosis. In particular, the onset and duration of symptoms and exacerbating factors should be noted. Depending on the age of the child, much of this information may come from parents or other caregivers. In addition to history and physical examination, imaging is critical to diagnosis and treatment planning. CT and MRI are the primary imaging modalities used when a skull base lesion is suspected. CT provides greater bony detail and illustration of sinus disease, whereas MRI provides greater soft tissue detail and is helpful for evaluating the brain parenchyma and meninges. The two modalities are frequently used in a complementary fashion.^{2,3} CT scans in particular should be performed judiciously, with described dose-reduction strategies, especially in younger children.⁴ Angiography remains the benchmark for diagnosis of suspected vascular lesions. Although efforts must be made to eliminate unnecessary radiation exposure in children, as many as 37% of these lesions may have some intracranial involvement that necessitates radiographic imaging.⁵

Tumors of the skull base may be divided anatomically into those involving the anterior, middle, or posterior fossa. Tumors of the anterior fossa are most likely to present to the plastic surgeon, given their location and propensity to present with facial signs and symptoms. These lesions are also the most likely to require plastic surgical expertise with craniofacial surgical approaches. However, regardless of who these patients see, a multidisciplinary team approach is quickly becoming the standard for treatment. Plastic surgeons are often called on to assist with a surgical approach to the cranial base because of their expertise with soft tissue management and experience with complex osteotomies.

LESIONS IN THE ANTERIOR FOSSA

Cranial base lesions in children are rare, and in particular lesions of the anterior fossa are much less common than those in adults. Lesions in this region may be characterized by their natural history as congenital, benign, or malignant (Box 39-1). Surgical planning for resection of these

Table 39-1 Encephalocele Classification Based on Anatomic Location

Anterior/sincipital	Nasofrontal Nasoethmoidal Nasoorbital
Basal	Sphenoorbital Sphenomaxillary Sphenoethmoidal Transethmoidal Transsphenoidal
Occipital	
Convexity	Parietal Temporal

lesions, when appropriate, includes a multidisciplinary team approach, with plastic surgeons providing the expertise with craniofacial approaches and hard and soft tissue reconstruction. These lesions will be the focus of this chapter.

Congenital Masses

Encephalocele

Encephalocele refers to a neural tube defect that allows the extracranial projection of neural tissue and meninges. They may be *primary* (congenital) or secondary. *Secondary encephaloceles* are typically the result of trauma or surgery. Many theories exist, but the cause of congenital encephaloceles is not well understood. Normally, a dural projection at the fonticulus nasofrontalis contacts the surface ectoderm and later becomes encircled by the foramen cecum. This projection later involutes, leaving only a fibrous structure that fills the foramen.⁶ In sincipital and basal encephaloceles, there is a pathologic patency of the foramen cecum beyond the second month of gestation that contains cranial contents. Lesions including only meninges may be referred to as *meningoceles* and those with both meninges and neural tissue as *meningoencephaloceles*. In addition to their contents, encephaloceles may be classified according to their anatomic location (Table 39-1).

Occipital encephaloceles are the most common subtype, representing approximately 75% of all encephaloceles, followed by anterior/sincipital (12%) and basal (8%).^{7,8} The incidence of these lesions varies geographically from 1 in 5000 to 1 in 40,000 live births; the highest prevalence (particularly of the anterior and basal subtypes) is in Southeast Asia.⁹ The reason for these differences has been hypothesized to be the result of socioeconomic, nutritional, and seasonal differences.⁶

Anterior encephaloceles present as external nasal masses and basal encephaloceles as internal nasal or palatal masses that may cause nasal obstruction, difficulty feeding, or obvious cosmetic deformity.⁷ They are pale or bluish, compressible masses that transilluminate on physical examination. Encephaloceles pulsate and expand with straining, crying, or compression of the jugular vein (the Furstenberg test), which can differentiate them from other congenital midline nasal lesions. Nasendoscopy may be necessary to adequately assess the appearance and extent of these lesions. If an encephalocele is suspected, in addition to physical examination, imaging with CT or MRI can confirm diagnosis. Biopsy or aspiration should be avoided to prevent meningitis or CSF leak (Fig. 39-1).

Although these lesions are benign with no malignant degeneration potential and a slow growth rate, early surgical excision by a multidisciplinary team is the treatment of choice for encephaloceles to prevent continued facial distortion. Surgical goals include a reduction of

Fig. 39-1 Transethmoidal nasal encephalocele.

normal-appearing neural tissue into its normal anatomic location, watertight dural closure, and improved cosmesis. In patients with significant hypertelorism, orbital translocation may be necessary.^{10,11}

Glioma

Gliomas are rare lesions that are clinically similar to encephaloceles. They consist of neural tissue present at the nasal base and are thought to develop in a similar manner to encephaloceles. Gliomas, however, lack the intracranial connection of encephaloceles and exist as an isolated nest of glial tissue (Fig. 39-2). There is a male/female ratio of 3:2 with no familial predisposition.⁷ Gliomas are classified as extranasal (60%), intranasal (30%), or combined (10%).¹²

Gliomas present and should be worked up in the same manner as encephaloceles. Differences on physical examination include that gliomas are firm reddish masses that do not transilluminate. Also, findings of the Furstenberg test are negative on physical examination—there should be no change in the lesions with straining or crying. Imaging will verify the lack of intracranial connection, but 10% to 25% have a fibrous stalk with an associated bony defect.⁷ As with encephaloceles, surgical excision is the management of choice, with a goal of improving appearance and preventing infection.

Nasal Dermoid

Nasal dermoid is the most common congenital midline lesion. Although incompletely understood, these lesions form during nasal development, probably when the dural ectoderm recedes from the surface ectoderm. Nasal ectodermal elements may be pulled inward, forming a sinus tract or cyst containing ectodermal and mesodermal elements.^{13,14} Nasal dermoids are typically seen in the first several years of life; they have a male predominance and no familial predisposition.¹⁴ They account for 1% to 3% of all dermoids and 4% to 12% of head and neck dermoids.^{13,15}

Nasal dermoids present as midline nasal masses and may secrete sebaceous material or become serially infected. There may or may not be a visible punctum, but a punctum with hair growing from it is pathognomonic for a nasal dermoid. Intracranial extension has been reported in 17% to 45% of nasal dermoid lesions. Thus investigation with CT or MRI imaging, in addition to history-taking and a physical examination, is warranted.¹³⁻¹⁶ On imaging, bifidity of the

Fig. 39-2 A, Encephalocele. B, Glioma. C, Nasal dermoid.

ethmoid plate or crista galli and enlargement of the foramen cecum are highly suggestive of intracranial involvement.¹⁷

The only treatment for these lesions is surgical excision (Fig. 39-3). If imaging results lead to suspicion of an intracranial extension, some surgeons advocate intraoperative examination and clinical diagnosis of extension; others perform an intraoperative frozen-section biopsy of the dermoid stalk base to assess whether dermal or epidermal elements are present, whereas others still recommend an intracranial approach and stalk resection.^{13,14,18}

Teratomas

Teratomas are germ cell tumors derived from all three germ layers that may be mature or immature. Immature teratomas have increased potential for malignant transformation (see Chapter 37 for further discussion of teratomas).

Benign Lesions

Juvenile Nasopharyngeal Angiofibroma

Juvenile nasopharyngeal angiofibroma is a benign, locally aggressive vascular tumor. These lesions are most frequently diagnosed in adolescent males. The most commonly used staging system is based on local tumor infiltration^{13,19,20} (Table 39-2 and Figs. 39-4 and 39-5). Patients typically present with complaints of nasal obstruction, epistaxis, facial pain, facial mass, or visual disturbance. At the time of initial consultation, patients have frequently experienced symptoms for several months, and 17% to 22% have intracranial extension at the time of diagnosis.^{20,21} The lesions appear as well-circumscribed, compressible, nasopharyngeal masses that are covered with mucosa. CT, MRI, and angiography may all be used to better delineate the tumor burden.

Table 39-2 Sessions/Radkowski Juvenile Nasopharyngeal Angiofibroma Staging

Stage	Features
I	Ia: Limited to nose/nasopharyngeal vault Ib: Extension into any sinus
II	IIa: Minimal extension into pterygomaxillary fissure IIb: Full involvement of pterygomaxillary fissure $\pm$ orbital bones IIc: Intratemporal fossa $\pm$ cheek or posterior to pterygoid plates
III	IIIa: Erosion of skull base with minimal intracranial activity IIIb: Extensive intracranial erosion $\pm$ cavernous sinus

Fig. 39-4 Acrylic craniofacial model demonstrating a large juvenile angiofibroma extending into the pterygopalatine fossa (*arrow*). **A**, Lateral view. **B**, Inferior view.

Fig. 39-5 Juvenile nasopharyngeal angiofibroma expanding the pterygopalatine fossa.

Most cases do not require biopsy. However, if biopsy is performed, potential hemorrhage should be anticipated, and it should take place in the operating room.²⁰

Surgical resection is the treatment of choice for nasopharyngeal carcinoma (NPC) but may be complicated by massive hemorrhage. Even with surgical resection, there is a 18% to 22% recurrence rate.^{20,21} Preoperative embolization has been shown to significantly decrease intraoperative blood loss and is recommended especially for higher stage lesions.²²⁻²⁴ Neoadjuvant therapy with flutamide and oral antiandrogen has had variable success in shrinking tumor size.^{25,26} Radiotherapy as both adjuvant and primary treatment has shown promise in decreasing tumor size in patients with extensive disease but has not gained widespread use because of complications such as hypopituitarism, malignant transformation, and cataracts.^{27,28}

Fibrous Dysplasia

Fibrous dysplasia is a benign osseous developmental disorder in which normal bone matrix is replaced by fibrous stroma and disorganized bony trabeculae. It may be monostotic (70%), polyostotic (30%), or part of McCune-Albright syndrome.²⁹ The disease process most frequently affects the proximal femoral metaphysis and the skull base. *McCune-Albright syndrome* was traditionally described as the trio of polyostotic fibrous dysplasia, skin hyperpigmentation, and precocious puberty. More accurately, it is now known to involve fibrous dysplasia in conjunction with an extraskeletal manifestation, including several other endocrinopathies (hyperthyroidism, growth hormone excess, and Cushing syndrome).³⁰ Inheritance is sporadic and caused by an activation mutation that ultimately impairs full osteoblastic differentiation.³¹ Although these lesions are benign, there has been reported malignant transformation (less than 1%), typically to osteogenic sarcoma.³² Fibrous dysplasia is usually diagnosed in childhood, and 90% of craniofacial lesions are present before age 5 years.³³ In general, these lesions may cause deformity, pain, stiffness, and pathologic fracture. With skull base lesions, dysplastic tissue may cause cranial and optic nerve compression, with resultant cranial neuropathies and even blindness.

Workup of these lesions should include ophthalmology and audiology evaluation. CT scan is the imaging modality of choice. Findings of histologic examination in children have a typical ground-glass appearance. Fibrous dysplasia may be treated medically with bisphosphonates or surgical excision. In the case of craniofacial lesions, medical management has not proved effective. Surgical excision is suggested in the case of significant deformity or neurologic deficit.¹¹ Both conservative subtotal excision and radical resection with immediate reconstruction are acceptable surgical approaches. Adjuvant radiotherapy is not advised because of the increased risk of malignant transformation³² (Fig. 39-6).

Malignant Lesions

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma (NPC) is a malignancy of the nasopharyngeal epithelium. It is most commonly seen in adults (40 to 60 years of age), but in the pediatric population it is most commonly seen in males (10 to 20 years of age), with a male to female ratio of 1.8:1.^{34,35} The disease is rare, with an annual incidence of 0.8 to 1.3 per million in low-incidence regions and endemic regions, respectively. In North America, black children are overrepresented among pediatric cases of NPC, although it is not completely understood why. This malignancy has been classified into three subtypes by the World Health Organization³⁶ (Table 39-3). In children, type III is more prevalent, whereas type I is more common in adults.

In children NPC is treated based on the adult experience with the disease, but this malignancy varies in significant ways from NPC in adults. In children, there is a stronger association

Fig. 39-6 Fibrous dysplasia lesion of the cranial base.

Table 39-3 WHO Classification of Nasopharyngeal Carcinoma

Type I	Keratinizing squamous cell carcinoma	Keratin production
Type II	Nonkeratinizing epidermoid carcinoma	Cell bundles with fusiform nuclei and scant cytoplasm
Type III	Undifferentiated carcinoma	Undifferentiated round cells with prominent nucleoli

with Epstein-Barr virus infection, a higher proportion of undifferentiated carcinoma on histologic examination, and more cases of locoregionally advanced disease at the time of diagnosis.^{34,35} NPC may present as a neck mass, nasal obstruction, epistaxis, otalgia, otitis media, headache, or neurologic symptoms as a result of skull base erosion.^{34,37} Physical examination should include assessment of cervical lymph nodes and the cranial nerve. A lesion or lymph node biopsy may confirm the diagnosis. The extent of tumor invasion may be assessed radiologically with CT and MRI. NPC is frequently unresectable because of the anatomic location and the likelihood of presentation with cervical lymph node metastases.³⁷ Treatment of NPC is based on adult protocols and consists of combination radiotherapy to the nasopharynx and affected lymph nodes and chemotherapy.³⁸

Esthesioneuroblastoma

Esthesioneuroblastoma (olfactory neuroblastoma) is a malignant, small, round cell tumor of neuroectodermal origin arising from the olfactory epithelium.³⁹ It is rare in the general population, with an incidence of 0.1 per 100,000 in children younger than 15 years of age.⁴⁰ Despite that, it is the most common cancer of the nasal cavity in the pediatric population. Esthesioneuroblastoma has a bimodal age distribution, with peaks in children ages 11 to 20 and adults ages 51 to 60.⁴¹ There does not appear to be a sex predisposition. Staging of these lesions was originally based on the anatomic extent of the disease, and this is still the most commonly used staging system, although more recent TNM staging has also been adopted^{42,43} (Table 39-4). The most common complaints of patients with esthesioneuroblastoma include nasal obstruction and epistaxis.

Table 39-4 Kadish-Morita Staging of Esthesioneuroblastoma

Stage	Feature
A	Tumor limited to nasal cavity
B	Tumor limited to nasal cavity and paranasal sinuses
C	Tumor extends beyond nasal cavity and paranasal sinuses
D	Tumor with neck or distant metastases

Fig. 39-7 An MRI of esthesioneuroblastoma invading the anterior skull base, frontal lobe, nasal cavity, and orbit.

On examination, these lesions appear to be reddish or gray tumors arising in the upper nasal fossa and may bleed easily with manipulation (Fig. 39-7). Workup of these lesions includes imaging with CT, MRI, and biopsy. Single, double, and triple modality (surgery, radiation, and chemotherapy) treatment protocols have been used, and surgical excision plus radiotherapy has the highest cure rate.³⁹ Regardless of therapy, prognostic factors include histologic grading and the presence of cervical lymph node metastases.³⁹

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common soft tissue sarcoma in children. Thirty-five percent of those patients who have a diagnosis of rhabdomyosarcoma present with a head and neck tumor (Fig. 39-8) (see Chapter 37 for further discussion of rhabdomyosarcoma).

SURGICAL APPROACHES

Advances in surgical approaches to the anterior cranial base have dramatically improved our ability to access these lesions and improve patient prognosis. Various techniques may be used to expose lesions of the cranial base. In general, both intracranial and extracranial approaches may be used. An exclusive intracranial or extracranial approach may be sufficient in cases of small lesions in a favorable location. Most of the time, however, a combined intracranial and extracranial

Fig. 39-8 Rhabdomyosarcoma of the infratemporal fossa.

Fig. 39-9 A, Markings for nasofrontal osteotomy. B, Bone flaps. C, Bone flaps replaced with bone graft.

approach is necessary. Approaches may be viewed in terms of soft tissue handling and osteotomies used to access the cranial base.

Soft tissue exposure may be achieved with a combination of coronal, transfacial, and gingivobuccal sulcus incisions. A standard coronal incision provides access to the frontal bone, orbital roofs, and nasal bone. It is most commonly used to access the frontal bone for intracranial exposure through a frontal osteotomy or superior orbital osteotomy. A pericranial flap is frequently raised to obliterate dead space or to reestablish anatomic boundaries after resection (Fig. 39-9). A transfacial open rhinoplasty or lateral rhinotomy/Weber-Ferguson approach provides wide exposure of the maxilla, orbital floor, and zygoma. With this soft tissue exposure, a maxillectomy, palatal split, and LeFort I osteotomy may be performed to approach the cranial base. A LeFort I should be performed with caution in children with mixed dentition, because it may damage unerupted tooth buds. Transoral access with an upper gingivobuccal sulcus incision allows a facial degloving technique that avoids incisions on the face and provides access to the maxilla, orbital floor, and zygoma. After degloving, maxillectomy, ethmoidectomy, and LeFort I osteotomy may be performed. Finally, the endoscopic endonasal approach to the anterior skull base has become increasingly performed as technique, imaging, and instrumentation have improved. It may be

used alone, particularly for extradural lesions of the skull base. It may also be used in conjunction with craniotomy.

CONCLUSION

Cranial base masses are best managed by a multidisciplinary team, particularly malignant lesions that require a combination of medical and surgical management and long-term follow-up. Cranial base masses have multiple causes, including congenital, benign, and malignant lesions. Thorough investigation, including the use of CT and MRI scanning, should be undertaken to make a diagnosis.

Encephaloceles, nasal dermoids, and gliomas are congenital lesions that may be diagnosed at birth. As with most congenital lesions, some remain undiagnosed until they become secondarily infected in childhood or later. Despite the name, benign tumors can be extremely destructive. Depending on their location, they can cause distortions of the overlying craniofacial skeleton and soft tissue or exert mass effect, causing visual or olfactory disturbance or cranial nerve neuropathy.

Malignant lesions may have the same effects, with the added risk of metastasis. When surgical intervention is indicated for these lesions, the most common approach remains the combined intracranial and extracranial approach, typically performed by a combination of plastic surgeons and neurosurgeons, which again underscores the importance of a team approach in the care of these patients.

KEY POINTS

- A multidisciplinary surgical team is the benchmark for treating patients with anterior cranial base lesions.
- Encephaloceles and gliomas are characterized by extracranial projection of neural tissue and are managed with surgical excision.
- Unlike dermoid cysts elsewhere, nasal dermoid cysts may have intracranial extension and should have imaging performed as a part of their workup.
- Benign cranial base tumors may be extremely locally destructive.
- Malignant cranial base tumors are rare in children. Management may be based on adult protocols despite differences in adult and pediatric disease characteristics.
- Typically, intracranial and extracranial approaches are combined to access anterior cranial base lesions.
- An endoscopic endonasal approach to the anterior cranial base has become increasingly popular.

Pediatric Craniofacial Fractures

Jesse A. Goldstein • Frederic White-Brown Deleyiannis
Shao Jiang • Joseph E. Losee

The American Academy of Pediatrics defines pediatric patients as those between birth and 21 years of age. The wide variation in function, anatomy, and growth potential that occurs within this age range makes any single approach to facial fractures in pediatric patients challenging. Even though fractures of the craniofacial skeleton are uncommon in children compared with adults, they are nonetheless frequently more difficult to treat because of significant anatomic differences and the potential for long-term growth and development.¹⁻⁶ Although the goals of treatment are the same as those for adults, the approaches to pediatric patients with facial trauma are often dramatically different.⁷⁻⁹ Even after years of advancement in craniofacial trauma treatment, many questions regarding pediatric patients remain unanswered. In this chapter, we will review the up-to-date literature, delineate the differences between adult and pediatric fracture patterns and management, and provide guidelines for the reconstruction of pediatric craniofacial fractures.

GROWTH AND DEVELOPMENT OF THE CRANIOFACIAL SKELETON

Understanding the centers of growth and development of the craniofacial skeleton is crucial to the ability to treat pediatric craniofacial trauma. Within the craniofacial skeleton, there are significant regional differences in growth patterns that continue to change throughout development. At birth, the cranial/facial proportion is 8:1. This ratio becomes 4:1 at around 5 years of age and 2:1 in adulthood.¹⁰ The growth of the neurocranium is 25% complete at birth, 75% by 2 years, and 95% by 10 years of age. In comparison, facial growth is only 65% complete at 10 years of age.¹⁰⁻¹³ Cranial growth is a continuous process that occurs in a defined period of time

and is essentially dictated by brain expansion under the influence of the cranial sutures. Indeed, the brain's volume triples by the end of the first year of life. The sutures gradually narrow, and the fontanelles are closed in sequence. This rapid growth occurs until 3 years of age and then dissipates into adulthood.¹⁰

In contrast, facial growth demonstrates a drastically different pattern of discontinuous growth until puberty is complete. Multiple mechanisms, such as facial synchondroses, sutures, and apposition and resorption, play roles in this process. At 3 months of age, the facial dimensions are 40% of those in adults, and they become 70% by 4 years and 80% by 5 years of age.¹⁰ At approximately 5 years, growth slows dramatically until the beginning of puberty, at which point accelerated growth occurs mediated by increased hormonal input. At 17 years, facial growth slows down again and eventually halts.

Upper facial skeletal growth occurs as a result of cerebral and ocular growth. Orbital expansion is complete by 6 to 8 years of age¹⁰; the frontal sinus becomes visible by 5 years and obtains complete aeration well after puberty. Midfacial growth is associated with dental development. By 2 years of age, transverse maxillary growth is near complete, whereas palatal and midline maxillary suture growth ceases between 8 and 12 years. At 12 years of age, pneumatization of the maxillary sinus occurs, along with dental eruption.^{10,12,13} Lower facial growth also shows sequential growth. The mandibular symphysis fuses completely by 2 years of age when the deciduous teeth are erupting. The primary growth centers of the mandible are thought to be the condyles, and they contribute to vertical growth, activated by muscular activities. These activities place stress on the periosteum, which in turn causes apposition and resorption of bone, creating mandibular growth in all other directions.^{9-11,13,14}

EPIDEMIOLOGY

Although the incidence of facial trauma is higher in children than in adults, the incidence of pediatric craniofacial fractures is much lower.^{15,16} Rowe² reported that only 1% of all facial fractures occurred in children less than 6 years of age. His findings have been echoed by McCoy et al,¹ Panagopoulos,¹⁷ Kaban et al,¹⁸ and others. However, most of these reports were made before CT was used to evaluate pediatric facial trauma, and therefore they likely underestimated the incidence of pediatric facial fractures.¹⁹ Several factors contribute to the overall low incidence of pediatric craniofacial fractures. First, infants and young children usually live in a protected environment; therefore the chance of trauma with significant impact is lower.¹⁰ As children grow older and begin to play independently and participate in sports, the risk of facial trauma increases. Second, unlike adults, children have a lower facial mass/cranium ratio and are therefore much more likely to sustain skull fractures and head injuries than facial fractures.^{10,20,21} Third, the pediatric facial skeleton is quite elastic because of immaturity, lack of sinuses, a higher percentage of cancellous bone, and the presence of cartilaginous sutures and growth centers. These factors allow pediatric facial bones to absorb more energy during impact without fracturing than adult facial bones.

The pediatric population varies in its distribution of facial fractures. For example, boys are twice as likely as girls to sustain facial fractures. In addition, the 6- to 12-year-old age group is more prone to facial fractures than any other age group. This is likely because the presence of mixed dentition and a higher tooth-to-bone ratio weakens bone.²² Other variations in fracture distribution with respect to age are likely associated with the decrease of the cranial/facial ratio that results in a more prominent face as the child grows.^{11,16,18} In addition, as the facial skeleton matures it becomes increasingly mineralized and pneumatized and therefore more prone to fracture. As pediatric patients age, there is a downward shift (superior-inferior) of the craniofacial trauma fracture pattern. Frontal skull and orbital fractures have a higher incidence in the new-

Fig. 40-1 A, Coronal CT scan showing a left-sided oblique craniofacial fracture pattern. B, Axial CT scan showing a right-sided oblique craniofacial fracture pattern.

born to 5-year-old age group, whereas midface and mandibular fractures have a higher incidence in the 6- to 16-year-old age group.²³ The nose and mandible account for most reported facial fractures in older children, which is likely because of their prominence.¹⁹ McCoy et al¹ and Bales et al⁷ found that mandible fractures were more common than nasal fractures, whereas Kaban et al¹⁸ reported the opposite. Midface fractures, including orbital, zygomatic/malar, and maxillary, are less common, as reported by both Kaban et al¹⁸ and McCoy et al.¹ In a recent analysis of 772 fractures in patients presenting to the emergency room of a level 3 trauma center, Grunwaldt et al²³ found that the highest fracture rate was in older patients, with 48% of fractures occurring in 12- to 18-year-old patients. In addition, younger patients were more likely to have frontal and orbital fractures caused by falls or motor vehicle collisions (MVCs), whereas older patients were more likely to sustain maxillary, nasal, and mandible fractures as a result of violence/assault, MVCs, and sports.²³⁻²⁵

When subjected to equal force, children develop incomplete greenstick fractures more often than adults.^{19,26,27} This is because the increased elasticity of the less mineralized and pneumatized pediatric skeleton and greater cancellous-to-cortical bone ratio add much more flexibility to the mandible and maxilla. These factors also result in unique fracture patterns seen in children; for example, it has been reported that more oblique craniofacial fracture patterns are found in immature facial trauma patients²⁷ (Fig. 40-1). The classic LeFort fracture patterns that are seen in mature craniofacial skeletons are rarely found in immature patients.

Causative mechanisms of pediatric facial fractures include motor vehicle accidents (MVAs; 50%), falls (23%), and sports (15%).⁶ Assaults represent a much less contributing factor⁴; however, violence-related facial fractures are more likely in older male patients of lower socioeconomic status.²⁴ There is a marked seasonal variation of pediatric facial fractures, which peaks in July. Recently, all-terrain vehicles (ATVs) have become an increasingly more common cause of pediatric facial fractures.²² Together, MVAs and ATV accidents cause more severe midface fractures than any other mechanism. This is especially evident in adolescents.²² Fortunately, child abuse is a rare cause of pediatric facial fractures, but it should be seriously considered as a cause in patients with associated unexplained long bone fractures.

DIAGNOSIS

Diagnosis of pediatric facial fractures is usually challenging. One must maintain a high degree of suspicion, especially in the presence of injuries to major organ systems. It is not unusual to have a patient who is unable to cooperate accompanied by anxious parents in the emergency department, which may necessitate sedated examination when safely possible. A history must be carefully obtained from both the parents and any witnesses to the incident, along with emergency medical support personnel. Preinjury photographs of the child, dental records, and models from the child's dentist and orthodontist are often helpful when treating children with facial fractures.

Plastic surgeons must work closely with the physician team to coordinate the care of a child with multiple injuries, following the Advanced Trauma Life Support protocol. The examination of the cervical spine is especially important in children with trauma. There is a reported 10% associated risk of concomitant craniofacial trauma and cervical spine injury.²⁸

Examination of a patient with craniofacial trauma should begin by observing the overall condition of the patient. Alertness and orientation should be carefully documented. A low threshold should be maintained for neurosurgical consultation in children with craniofacial trauma, because 75% of frontal sinus fractures are accompanied by loss of consciousness,¹⁹ and close to half of patients with facial fractures have accompanying neurologic injuries.²³ The airway should be thoroughly evaluated. Endotracheal intubation in these patients is uniquely challenging, because cervical spine clearance is often not entirely possible and may also be complicated by fractures of the mandible or midface. Pediatric anesthesia support for nasal intubation over a flexible endoscope may be performed with limited cervical spine motion and may be the best way to establish a nonsurgical airway.²⁸ If all else fails, tracheostomy or cricothyrotomy can be used.

Physical examination begins with the head. Careful palpation of the skull should be carried out after adequate cleansing of any scalp wounds, and this may require local anesthesia. Any scalp lacerations must be washed out and carefully examined for underlying skull fracture. Next, attention is given to the superior orbital ridge. Fractures in this region can often cause paresthesia of the forehead and may be associated with traumatic ptosis of the brow. It is important to realize that in young patients without a frontal sinus, forehead and supraorbital ridge fractures are essentially anterior cranial base fractures.

Orbital examination is extremely important, because there is a significantly higher percentage of ocular trauma and blinding injuries in this population compared with adults. Studies have reported as high as a 3% blindness rate in children with orbital fractures.²⁹ Consultation with a pediatric ophthalmologist should always be obtained when children present with periorbital trauma. Subconjunctival hematomas are pathognomonic for orbital fractures, because the conjunctiva is contiguous with the orbital periosteum; therefore patients with these conditions must be assumed to have an orbital fracture until a CT scan is obtained. Bilateral vision should be carefully documented, and when possible, evidence of afferent papillary defects is verified and documented. Extraocular movements should be tested voluntarily in conscious patients, and forced duction testing should be performed with unconscious patients and all patients undergoing surgery. Total ophthalmoplegia, along with upper eyelid ptosis and paresthesia in the V1 distribution, indicates the presence of superior orbital fissure syndrome. If blindness is present in addition to these findings, then orbital apex syndrome is diagnosed. Both these conditions are ophthalmologic emergencies that may require urgent surgical decompression and high-dose steroid therapy. The medial canthal tendons should be tested in patients with periorbital trauma. This is done with the bow-string test, which is performed by pinching the eyelids and distracting them laterally to check the stability or mobility of the medial canthus. Intercanthal distance

should be measured and documented. Any periorbital lacerations medial to the lacrimal puncta indicate potential damage to the lacrimal drainage system.

Examination of the nose begins with the nasal root and continues caudally. Deviation of nasal bones should be evaluated, as well as compressibility of the nasal dorsum. Any rhinorrhea or nasal discharge should raise suspicion of a CSF leak, therefore prompting a CT scan and consultation with the neurosurgical staff. A thorough intranasal examination should be carried out with a nasal speculum and an adequate light source, and any septal hematomas should be treated promptly.

Examination of the midface begins with the inferior orbital rims. Fractures in this region are often associated with cheek paresthesia and a step deformity that can be felt with manual palpation. The entire zygoma should be palpated. Fractures of the zygoma often result in lateral canthal dystopia and a loss of malar prominence. Midface stability should be tested by attempting manual distraction of the maxilla while stabilizing the head; any independent movement of the maxilla may indicate a midface fracture. However, if the patient has an obviously mobile midface, one should refrain from manipulating it more, because this may cause optic nerve trauma. Occlusion is also an important diagnostic maneuver when one is evaluating the midface, and abnormal occlusal findings should prompt further radiologic studies. During examination of the midface, attention should also be given to the ears. Hemotympanum, as well as a mastoid hematoma (Battle's sign), may indicate a basilar skull fracture. External trauma, including subperichondrial hematomas, requires prompt treatment.

Lower craniofacial skeleton examination begins with the mandible; the patient's own subjective assessment of occlusion is obtained whenever possible. Subjective malocclusion is a sensitive indicator of occlusal disorders. Objectively, malalignment of the dental arch and open bites are indicative of jaw fractures (Fig. 40-2); however, patients with mixed dentition often have such preexisting malocclusions, which is normal for their stage of development. Angle's classification should be used to document findings, and any evidence of malocclusion should prompt obtaining a panoramic film and/or a CT scan. Chin paresthesia is found often in patients with parasymphysal fractures. Palpation of the mandible starts at the temporomandibular joint (TMJ) and ends at the symphysis. A high index of suspicion must always be maintained with children, because pain during palpation is often the only indicator of facial fractures.

Diagnostic imaging to evaluate pediatric facial fractures has evolved, and in modern practice sophisticated CT algorithms have limited the role of plain radiography, because the pediatric facial skeleton is immature and has a high cancellous/cortical bone ratio. Fine-cut spiral CT scans

Fig. 40-2 Malalignment of the mandibular dental arch, which is indicative of fracture.

from skull to mandible should be used whenever possible. True coronal images are ideal, although if unable to clear the cervical spine, reconstructed coronal images, based on the axial CT scan, can often suffice. Three-dimensional reconstructions of fine-cut CT scans are exceedingly useful for diagnosing fractures and treatment planning. The Panorex is the single plain film that remains useful to evaluate pediatric patients who are able to cooperate for the study.

TREATMENT OF FACIAL FRACTURES: UNIQUE FACTORS

Managing pediatric facial fractures is often difficult, because the goal of obtaining the best possible reduction and fixation must be balanced with potential growth disturbances associated with open surgical approaches to the pediatric facial skeleton.¹⁰ Evidence of facial growth restriction after wide subperiosteal dissection has been reported³⁰; however, Bartlett et al³¹ reported no growth disturbances after wide undermining of the frontoorbital region, such as from the treatment of craniosynostosis.

Different areas within the facial skeleton demonstrate different healing properties. In a growing child, the condyles of the mandible have an excellent ability to remodel, and therefore a conservative approach may often be taken with pediatric condylar fractures. It is prudent to accept minor occlusal disturbances in a growing child while the surgeon attempts to treat fractures conservatively, because these may be corrected with future orthodontic treatment. Other areas, such as the orbit, may not tolerate malunion so well and therefore may require adequate exposure for internal fixation. It is imperative that surgeons clearly communicate to parents the potential risks of growth disturbances that the fracture itself, along with its surgical correction, may impose. In addition, there is an increased risk to unerupted and developing tooth buds in the jaws of pediatric patients. Communication helps parents to understand the need for long-term follow-up.

Another unique controversy in the treatment of pediatric facial fractures is the use of alloplastic materials and rigid fixation. The advantages of titanium miniplate and screw fixation include increased control and decreased mobility of bony fragments and improved contour postoperatively.³² The disadvantages of using these plates and screws include hardware migration and potential growth restriction.¹⁵ Yaremchuk et al³³ studied the effects of plate and screw fixation on the growing craniofacial primate skeleton with wire fixation, limited miniplate and screw fixation, and extensive miniplate and screw fixation. They found that a small but measurable visible change occurred in the growing primate skull after miniplate and screw fixation. The magnitude of these changes appears to increase with an increased amount of fixation hardware used.³³ Many have also noted that metallic hardware in a growing skull can translocate to the endocranial positions after craniofacial surgery (Fig. 40-3). Metallic wires and hardware have become embedded in the dura; however, to date this has only posed potential hazards. Because of these findings, many surgeons feel that only absorbable hardware is indicated for pediatric patients.³⁴ In the past 15 years, resorbable fixation systems have become widely available and allow reasonable fracture fixation in the short term without limiting growth in the long term.³⁴

Pediatric patients with facial fractures often do not display the standard LeFort fracture patterns found in adult patients.³⁵ This oblique fracture pattern is often seen with high-velocity trauma, as described by Moore et al²⁷ (see Fig. 40-1). This fracture pattern runs obliquely from the cranial base to the frontal bone with extension into the orbit and maxilla. Extension to the mandible is rare. This pattern is supposedly caused by the absence of rigid bony buttresses that are present in adults.¹⁰

Fig. 40-3 Translocation of metallic plate and screws to the endocranial side of the skull.

TREATMENT OF FRACTURES

Skull and Forehead

Children have larger cranium-to-face ratios than do adults. This is in addition to the more elastic nature of pediatric bone and the lack of a developed frontal sinus,⁵ which begins its pneumatization around 5 years of age and completes the process at about 20 years of age.³⁶ Because of this, children who sustain significant force to the skull frequently have fractures extending to the cranial base.⁸ Mann et al³⁷ reported that in 1297 pediatric skull fractures, the incidence of associated intracranial injuries was directly related to age. Whereas children younger than the age of 2 years with open skull fractures had a negligible chance of developing intracranial hematomas, 15-year-old children had an incidence of intracranial hematoma equivalent to adults.³⁷ Bonfield et al³⁸ revived 897 pediatric skull fracture patients, the vast majority of which did not require intervention. Factors associated with the need for intervention included direct blow to the head with an object or an MVC. Although children with head injuries generally have a better chance of survival than adults, the long-term sequelae are more significant.

Skull fractures often occur in an oblique orientation in pediatric patients, with a fracture originating at the site of impact, extending to the supraorbital foramen, and progressing to involve the orbit and zygoma, resulting in an oblique craniofacial fracture.¹⁹ Oblique fracture patterns can be exceedingly difficult to treat, because a craniotomy is required to reduce the often depressed and impacted frontotemporal skull fracture that is contiguous with the facial fracture (see Fig. 40-1). The most common mechanisms of pediatric skull fractures are MVAs, followed by falls and fights. There is a 20% correlation between long bone injuries and skull fracture in this population.

Diagnosis of skull, forehead, and cranial base fractures should be done by a careful physical examination, followed by a CT scan. A CT scan is necessary because of the high incidence of associated intracranial injuries. Any scalp laceration should be explored under sterile conditions to determine bony continuity and to rule out skull fracture. Eyelid hematoma, acute hearing loss, hemotympanum, or cranial nerve palsy are often present with basilar skull fractures.

Unique to pediatric craniofacial fractures is the *growing skull fracture*.³⁹⁻⁴¹ A growing skull fracture is thought to occur when the fracture is associated with a dural tear. The dural diastasis allows brain pulsations to slowly separate the fracture edges, resulting in nonunion and “growth” of the fracture. One site for growing skull fractures is the frontal bone with extension into the supraorbital ridge, resulting in orbital changes such as bony orbital expansion, vertical orbital

dystopia, and pulsatile exophthalmos.⁴¹ Contrary to previous reports,⁴² a recent series published by Losee et al⁴³ demonstrated growing skull fractures in more than 4% of all pediatric orbital fractures and 15% of orbital roof fractures. For this reason, long-term follow-up is critical in this patient population (Fig. 40-4).

Frontal bone, frontal sinus, and cranial base fracture treatment should achieve four goals^{19,44}:

1. Isolation of intracranial structures (for example, separation of the brain from the nose)
2. Cessation of CSF leakage
3. Prevention of posttraumatic infections (for example, pyocele and mucocele)
4. Restoration of facial contour

Fig. 40-4 A, A 10-year-old with a growing skull fracture of the left forehead and orbit after trauma. B, Three-dimensional CT scan revealing the fracture. C, Intraoperative view of the growing skull fracture. D, Reconstructed fracture. E, One-year follow-up with normal forehead and orbital morphologic structure.

Indications for surgical intervention include persistent CSF leakage (more than 4 days), intracranial/extracranial hematoma, significant bony displacement, and deformed facial contour. Treatment of these fractures often requires the assistance of neurosurgical colleagues in a combined approach. Nondisplaced or minimally displaced frontal bone fractures are often treated nonoperatively. Displaced fractures are treated with a coronal incision approach, access by craniotomy, and fixation with either resorbable plating systems in young patients or wires or titanium plating systems in those patients near adulthood (Fig. 40-5). When the frontal sinus is pneumatized, the treatment should be specific to address each fracture pattern and to ensure either a “safe sinus” by confirming adequate drainage and prevention of future mucoceles or obliteration/cranialization of the sinus. With advances in the treatment of frontal sinus disease, placement of frontonasal duct stents may potentially help to maintain patency. For fractures involving the frontonasal ducts, the frontal sinus is usually obliterated or cranialized. All sinus mucosa is carefully removed with loupe magnification, methylene blue dye, and a burr.¹⁹

Incomplete mucosal removal increases the risk that mucocoele, mucopyocele, and brain abscesses will occur several years after the initial surgery. When the sinus mucosa is completely removed, the space is left either empty or obliterated. Various autologous materials have been used to obliterate the frontal sinus, including bone, fascia, pericranium, and fat. We feel that the

Fig. 40-5 A, A 13-year-old with a frontal bone fracture after an ATV accident. B, Frontal bone pieces mapped out. C, Reconstruction with absorbable plates. D, Six-month follow-up after reconstruction.

procedure of choice for sinus obliteration involves the use of cancellous bone from the iliac crest, taking care to obliterate the frontonasal ducts. When there are comminuted fractures of the posterior wall of the sinus, with or without CSF leaks, the sinus is often cranialized. Cranialization of the sinus includes removal of the posterior wall, complete removal of all mucosa, blocking the frontonasal ducts with bone grafts, and completing the isolation of the intracranial contents with a pericranial and/or a galeal flap.

If the nasocranial defect is large, an additional inferior or nasal approach can be used to separate the nose from the brain. Galeal grafts or AlloDerm (LifeCell Corp.) can be endoscopically placed in the superiormost nasal vault recess at the defect with tissue adhesives and glues. A course of nasal packing completes this technique. The incidence of meningitis after surgical treatment of frontal sinus fractures in pediatric patients is about 5%.⁴⁵ Long-term follow-up of children with frontal bone/sinus fractures is required to ensure that their frontal sinuses have adequate drainage as they grow. Imaging is often suggested for follow-up visits. Although routines may vary, it is reasonable to repeat a CT or MRI scan every 3 to 5 years to rule out mucocele formation.

For pediatric patients with a cranial injury that involves bone loss, the task of reconstruction is difficult. The procedure of choice for calvarial reconstruction remains the use of split calvarial grafts; however, this option is unavailable to younger patients. The diploic space between the inner and outer tables of the calvarium begins to be evident at 3 years of age and can be fully apparent by 9 years of age. Therefore, when harvesting split calvarial bone grafts in children younger than 9 years of age, a full-thickness cranial bone graft should be obtained, and the split should be performed on the back table if possible.

After the age of 9 years, *in situ* harvesting becomes much safer. The ribs and ilium also provide a source of autologous bone for calvarial reconstruction. Usually multiple ribs are harvested and split. Each segment is then contoured with bone-bending forceps and applied to the defect. However, rib grafts are plagued by high rates of resorption.⁴⁶ Although synthetic materials abound (for example, methylmethacrylate and titanium), it is best to use autologous material when possible in a growing child.⁴⁷ When synthetic materials are used, the age and growth potential of the child must be considered. This is only significant for calvarial reconstruction in the 2- to 10-year-old age group when children have lost their osteogenic potential and their diploic space is not developed enough for splitting.

In our experience, a bilaminate construct composed of absorbable mesh placed both intracranially and extracranially, interposed with a compact layer of demineralized bone matrix and chips or shavings of bone graft and used in primary craniofacial surgery, has led to bony regeneration, providing a stable reconstruction in patients of this age group. The surgeon must recognize that this technique is successful for primary calvarial defects with nonscarred or injured dura or scalp. In the compromised and/or scarred environment, this technique has demonstrated limited success⁴⁸ (Fig. 40-6). In addition, we have increasingly used custom porous polyethylene implants to reconstruct large cranial defects when soft tissue quality was uncompromised⁴⁹ (Fig. 40-7).

Orbital Fractures

Pediatric orbital trauma is rarely isolated and is often associated with zygomatic fractures.¹⁹ The orbit reaches adult size near the age of 7 years, and both the small maxillary sinuses and flexible bone contribute to a lower incidence of blowout fractures in children. Tooth buds provide support to the orbit in very young children, particularly in the inferior medial region of the floor. The most common causes of pediatric orbital fractures are MVAs; child abuse is second in prevalence. The separation of the frontozygomatic suture in the lateral orbital wall is quite common

in children, whereas it is uncommon in adults.¹⁹ In addition, the frontal sinus is absent before the age of 7 years. Therefore traumatic energy is transmitted to the floor of the anterior cranial vault, which is the orbital roof, causing isolated orbital roof fractures. When there is an isolated orbital floor fracture, children are prone to trapdoor-type fractures, in which the inferior rectus or inferior oblique muscle becomes trapped beneath the fractured segment, which has “snapped back” into position. This is one of the true surgical emergencies in pediatric facial trauma management (Fig. 40-8). Immediate surgical exploration and release of the trapped muscle are critical, because the muscle has an increased risk of ischemic injury in a relatively short period of time and can suffer permanent damage if not treated in a timely manner. Although pediatric orbital fractures are less common than in adults, there is a significantly higher incidence of blinding injuries in the pediatric population.²⁹

Therefore a higher index of suspicion for orbital injuries should be maintained for children with any evidence of periorbital trauma, and such patients should undergo a thorough ophthalmologic evaluation. The presence of periorbital ecchymosis or subconjunctival hemorrhage should alert the surgeon to the possibility of orbital fracture. The infraorbital nerve is often contused or trapped in its course along the orbital floor, resulting in hypoesthesia in its distribution. Palpation of the orbital rims may elicit pain and reveal step-off deformities. Diplopia and restricted extraocular eye movements can result from entrapment of periorbital soft tissue and/or extraocular muscles. CT examination of pediatric orbital fractures is crucial to both confirm the physical findings and delineate the fracture pattern.

The traditional absolute and relative indications for operative management of orbital floor fractures commonly used in the adult patient do not apply to pediatric patients. The goals of treating pediatric orbital fractures are to restore globe position and correct visually handicapping diplopia. Treatment should begin with pediatric ophthalmologic evaluation and coordination. With nondisplaced or minimally displaced fractures, a conservative approach with careful weekly follow-ups can often yield excellent results. For trauma to produce posttraumatic enophthalmos or vertical orbital dystopia, there must be a composite injury to the orbital bone and supporting structures (ligaments and periosteum). This composite injury allows the intraorbital volume to expand, creating changes in globe position. In our experience, pediatric patients are more likely to receive a traumatic injury that causes bony disruption but that does not lead to enophthalmos,

Fig. 40-8 Left-sided orbital floor trapdoor fracture with trapped muscle.

vertical orbital dystopia, or visually handicapping diplopia.⁴³ This may be a result of greater resiliency of the ocular supporting structures in pediatric patients.

Therefore we recommend that orbital fractures in the absence of acute enophthalmos and vertical orbital dystopia initially be approached conservatively with close surgical and ophthalmologic follow-up, regardless of the bony fracture pattern (Fig. 40-9). With malposition of the globe or persistent diplopia, the goals of surgical treatment should be restoration of orbital volume and release of all trapped soft tissue and muscle to correct globe position and diplopia. Early intervention is indicated when there is significant alteration of orbital form and volume, resulting in vertical orbital dystopia and/or enophthalmos, because delayed repair is often difficult in children—they heal fractures quickly.

Many approaches to the pediatric orbit have been described. A transconjunctival approach is preferred when available, because it has a lower incidence of ectropion and excellent postoperative cosmesis. If extended exposure is needed, a drawback of the transconjunctival approach is the need to perform an additional lateral cantholysis to approach the lateral orbital wall, and this may result in altered morphologic structure of the lateral canthal region. Alternatively, a subciliary or midlid incision can be used. Although the incidence of ectropion with this approach is slightly higher than that of the transconjunctival approach, the cosmesis is quite good in skilled hands. Infrequently an upper gingivobuccal sulcus incision is needed to adequately view and reduce infraorbital rim fractures.

Fig. 40-9 A, Right-sided medial orbital wall fracture treated conservatively. B, Frontal view and C, submental view at 6-month follow-up.

Fig. 40-10 Left-sided orbital reconstruction with split calvarial bone grafts.

When surgically treating orbital fractures, the surgeon must be keenly aware of the differential depth of the orbit to avoid injury to the optic nerve. After adequate mobilization of the orbital contents, the herniated soft tissues are reduced from the fracture defect. The perimeter of the bony defect must be fully delineated so adequate reduction can be ensured, and stable ledges are identified to place grafts. Bony fragments that may impede anatomic restoration are removed. The defect is then repaired with either an autologous split calvarial bone graft or synthetic material, such as resorbable mesh. In the growing craniofacial skeleton, every attempt should be made to use autologous methods of reconstruction. Split calvarial bone grafts or split rib provide excellent bone for orbital reconstruction (Fig. 40-10). Orbital bone grafts should be rigidly fixed, with the smooth cortical surface facing the intraorbital space. Rigid fixation of the orbital rims can be carried out with absorbable microplates. Alternative means of fracture fixation, including metallic microplates and screws or interfragmentary wire fixation, are available but should be used with caution in the growing craniofacial skeleton. Resuspension of the midfacial soft tissues is required to avoid postoperative soft tissue ptosis. Diplopia and ocular movement abnormalities in the immediate postoperative period often resolve, provided there is adequate reduction and release of all entrapped tissue. Monitoring vision often necessitates overnight stays for children undergoing surgical treatment of orbital fractures. Steroids can be given if significant intraorbital surgery is performed. Any ipsilateral eye pain that is unexpected or out of proportion, with or without change in vision, requires thorough examination and possible surgical reexploration.

Zygomaticomaxillary Fractures

Isolated classic zygomatic fractures are uncommon in children. The incidence of zygomatic fractures in pediatric facial trauma is 4.7% when isolated but increases to 16.3% when associated with orbital fractures¹ and are more common with increasing age.²³ This is likely because of the underdevelopment of the maxillary sinus in early childhood, which allows the zygomaticomaxillary buttress to provide rigid support. Significant force is required to cause a zygomatic fracture, because the immature bone is quite resilient. Fracture dislocation occurs through the zygomaticofrontal suture, downwardly displacing the zygoma and orbital floor and often resulting in an oblique craniofacial fracture pattern.¹⁹

The goal of treating pediatric zygomaticomaxillary fractures is restoration of preinjury facial appearance. Two functional deformities may result from significantly displaced zygomaticomaxillary fractures: *orbital dysmorphism* (enophthalmos and vertical orbital dystopia) and *malocclusion*. Nondisplaced or minimally displaced fractures are similarly treated with conservative care and close follow-up. For displaced zygomatic fractures, open reduction internal fixation is required. Surgical exposure is provided by an upper buccal sulcus incision combined with either a subciliary incision or subconjunctival incision with lateral cantholysis to approach the zygomaticofrontal suture.¹⁹ A brow or coronal incision is rarely needed to treat isolated zygomaticomaxillary fractures. Reduction of the fracture is obtained at the lateral orbital rim or zygomaticofrontal suture, the lateral orbital wall or greater wing of the sphenoid, the inferior orbital rim, and the zygomaticomaxillary buttress. The lateral orbital wall or greater sphenoid wing is the key to adequate reduction. After reduction, fixation at the zygomaticofrontal suture, inferior orbital rim, and zygomaticomaxillary buttress is performed, in that order, to adequately stabilize the reduced fracture. The orbital floor should be explored in comminuted zygomatic fractures before and after reduction to ensure that fixation did not change orbital floor stability or orbital volume. Care must be taken to avoid injury to developing tooth buds in young children. Postoperative malalignment of zygomatic fractures has been reported to reach 10%, and this is likely from open “nonreduction” and fixation. Complications are also more common with closed reductions.^{50,51}

Maxillary and Midface Fractures

Isolated midface fractures in children are rare.⁵² This is an effect of the prominence of the cranium and mandible, which generally absorb most of the impact during trauma. Therefore when midface fractures are seen in children, efforts should be made to identify other injuries, because the incidence of associated injuries ranges from 25% to as high as 88%.^{1,19,53,54} Because the classic buttresses are underdeveloped, pure LeFort fractures are very uncommon, and as previously described, children often have oblique patterns of craniofacial fracture.²⁷ The LeFort I fracture is rare, because the maxillary sinus is often not yet pneumatized, and unerupted teeth act as an internal support to the midface. Thus the force is transferred to the alveolus, resulting in tooth avulsion and alveolar fractures.⁵ A midface fracture occurring at the LeFort II level typically presents as a combined nasoorbital ethmoid and LeFort I maxillary fracture and is often unilateral. Midface fractures occurring at the LeFort III level are very uncommon in children and classically present as combined nasoorbital ethmoid and zygomaticomaxillary fractures. Bony injuries at this level present as multipiece midface fractures. In contrast, because the palatal suture is incompletely ossified, midline palatal fracture separations are common in children.¹⁹ The diagnosis of a midface fracture is made by the physical findings of maxillary mobility, bony step-offs, and malocclusion. Fine-cut CT scans should be used to delineate the injury and prepare for surgery. Intracranial injury must be ruled out before surgical intervention begins, because significant force is required to produce midface fractures in children.

Typically, a conservative approach should be taken with infants and young children who have minimally displaced or greenstick maxillary fractures, and this usually includes a liquid or soft diet. A conservative approach is possible because pediatric patients have rapid healing and the ability to remodel their fractures, and it allows the option of early orthodontic intervention to correct mild occlusal discrepancies. In older children and adolescents, a more classic approach should be used. If maxillomandibular fixation (MMF) is required, care must be taken to avoid injuring the developing tooth buds and subluxating or extracting primary teeth with conical roots. MMF can be difficult in infants and young children, and the surgeon must be creative to achieve rigid intermaxillary fixation (IMF). The options of circummandibular wiring and piriform aperture

drop wires can be used to secure fixation (Fig. 40-11). In addition, alternative techniques, such as “homemade IMF hooks,” (Fig. 40-12) can be fashioned as needed in the dental laboratory, tailored to the patient, and used with considerable ease and effectiveness. Also, if the dental units are present, arch bars can be placed during the period of primary or mixed dentition.⁵⁵ Proper occlusion must be obtained before fixation and checked periodically. Palatal fractures can often be treated with closed reduction and fixation with an orthodontically made palatal splint without rigid fixation. Cooperative interaction with pediatric dentists and orthodontists can often

Fig. 40-11 A, Piriform suspension wires used for maxillomandibular fixation. B, Mandibular border wires, similar to circummandibular wires, used for maxillomandibular fixation.

Fig. 40-12 A, “Homemade” IMF hooks. B, IMF hooks secured to the piriform region of the maxilla in a mixed dentition patient. C, IMF hooks secured to the inferior mandibular border. D, After closure with elastics in place.

save a significant amount of effort, especially if preoperative impressions and models were taken before injury and are available. In infants and children, the length of MMF is often less than the 6 weeks used for adult patients. After a shortened course of rigid MMF, dental elastics are used to maintain the desired occlusal relationship. Because there is significant risk of growth disturbance regardless of adequate treatment, parents of children with midface fractures must be informed of potential long-term growth effects and encouraged to follow up closely.

Nasal Fractures

Nasal fractures are the second most common facial fracture in children and can often involve the nasal bones and cartilages and the septum. Because of the significant presence of cartilage, a nasal fracture is often missed during examination in pediatric patients.⁵⁶ In children, the nasal bones can separate along an open midline suture, thus predisposing them to an “open book” type of fracture, which results in the nasal bones overriding the frontal process of the maxilla.¹⁰ Pediatric nasal fractures may have a significant impact on the growth and development of the facial skeleton, resulting in septal or nasal deviation, as well as midface hypoplasia. Even with early intervention and adequate reduction, cosmetic and functional deformities, such as deviations, dorsal humps, saddlenose deformities, and airway obstruction, still occur. Therefore the surgeon should discuss with parents the potential complications and the need for further corrective surgeries in the future. Unless significant symptomatic nasal obstruction is present, secondary nasal surgery should be performed after skeletal maturity has been reached.

It is often necessary for children to be under general anesthesia for adequate nasal examination and treatment. A complete intranasal examination is routinely required to thoroughly evaluate the septum. As with other pediatric facial fractures, plain radiographic films are grossly inadequate to diagnose nasal fractures in pediatric patients. Fine-cut CT scans provide the necessary information for complete diagnosis and treatment. It is prudent to treat open fractures and septal hematomas acutely and without delay, whereas other types of nasal fractures often require a short delay to allow swelling to decrease and reveal potential deformities. One unique injury found in pediatric nasal trauma is a hematoma between the upper lateral cartilages and nasal bones.^{19,56} Because these two structures are overlapped and loosely attached, the cartilages can easily detach, resulting in a hematoma between the cartilage and bone. This injury requires drainage through an intercartilaginous or subperiosteal incision.⁵⁶

An untreated septal hematoma can lead to pressure necrosis and diminished blood supply to the septal cartilage. This can result in either thickening or destruction of the septum and classic saddlenose deformity. Adequate drainage of a septal hematoma requires an incision through the mucoperichondrium on the side of the hematoma at the most dependent portion. When present bilaterally, bilateral mucoperichondrial incisions or resection of a small piece of the inferior septum through a unilateral incision can be used for drainage. Silicone intranasal splints and/or nasal packing can be used for postoperative septal compression during the healing phase.

Acute treatment of nasal fractures with closed reduction and external fixation often leads to suboptimal results in adults.⁵⁷ This is most likely caused by inadequate release of tension forces deviating the septum, nasal cartilages, and bony pyramid when closed reduction is used alone. Adequate treatment of a crooked nose usually requires a complete septorhinoplasty, including correcting any septal deviation and releasing deforming forces. However, aggressive nasal surgery in infants and children is still thought to have a negative impact on the growing facial skeleton. Because of this concern, we think that it is most appropriate to attempt closed reduction and external fixation of nasal fractures in the acute setting when there is obvious nasal bone deformity. This reduction of the nasal bones and septum should be attempted with the patient under sedation or general anesthesia. An Ash forceps is used to reduce and relocate the septum. A knife

handle or Boies elevator, placed endonasally and underneath the nasal bones, is combined with external digital pressure to reduce the nasal bones. Intranasal packing is often required to maintain the reduction and is used in conjunction with an external nasal splint. When intranasal packings are used, antibiotics should be given to avoid the potential risk of septic shock syndrome.⁵⁸ Because facial fractures heal quickly in younger children, splints are rarely needed after 5 days.

Mandibular Fractures

Mandibular fractures are the most common facial fractures reported in children, and this is likely because the bony mandible is prominent. The reported incidence of mandible fractures is between 20% and 40% of all pediatric facial fractures.^{21,59} This high incidence may also be caused by the probable underreporting of nasal and dentoalveolar fractures. Mandibular fractures are uncommon in children younger than 6 years, and therefore their presence should alert the physician to look for concomitant injuries. The incidence of pediatric mandibular fractures increases between 6 and 15 years of age.³ As children grow, the distribution of fractures in the various regions of the mandible also changes. Condylar fractures are common during the first 6 years of life (43.4%), but this decreases to 7% to 10% in children ages 13 to 18 years.^{5,60} In children older than 15 years, 76% of mandibular fractures occur in the regions of the angle and body.⁶⁰ The characteristics of pediatric mandibular fractures also differ from those in adults and include more greenstick fractures and long irregular sagittal fractures.⁶¹ All of these issues should be taken into consideration before the management of pediatric mandibular fractures is undertaken. Attention should be given to cervical spine injuries, because the force required to produce a fracture is significant.

The most common symptoms of pediatric mandibular fracture are pain and malocclusion. The patient often complains that his or her teeth do not come together. Drooling and trismus, with a decreased maximal incisal opening, are often present. A dental step-off, with bleeding, swelling, and ecchymosis, is routinely found intraorally (see Fig. 40-2). In addition, classic patterns of malocclusion are easily noted. Although bilateral condylar fractures usually result in an anterior open bite, unilateral condylar fractures often present with contralateral posterior open bites. With condylar neck fractures, the condylar head is often medially displaced from the pull of the pterygoid muscles. The TMJ can be assessed by placing fingers in the external auditory canal while the child opens and closes his or her mouth. Another useful technique to diagnose pediatric mandible fracture is simply to place the heel of the examiner's hand on the child's symphysis and ask the child to push against it with his or her chin. If there is significant pain, then the suspicion of mandible fracture should be raised. Although a Panorex is useful in older children, a CT scan is the most reliable way to delineate mandibular fractures in the pediatric population.

To safely treat children who have mandibular fractures, one must understand basic dental development. The deciduous mandibular incisors first appear at approximately 6 months of age, followed by eruption of the molars and then the cuspids. Even with their conical shape, primary tooth roots are strong enough for interdental wiring between 3 and 6 years of age, but care should be taken when circumdental wires are placed.⁵⁵ Mixed dentition is present between 6 and 12 years of age, and the resorption of primary tooth roots, along with the underdevelopment of permanent tooth roots, creates a unique challenge for securing arch bars in this age group. Therefore it is helpful to perform a Panorex study with these patients to delineate teeth with stable roots. The surgeon must be creative and well versed in all manner of interdental fixation, such as acrylic splints, circummandibular wiring, drop piriform aperture suspension wiring, and nasal spine suspension wiring. Although teeth are available for placement of circumdental wires and arch bars in younger patients (3 to 4 years of age), their inability to understand and cooperate can often result in disruption of IMF in the early postoperative period because of their constant struggle against

Fig. 40-13 A, Child shown in a cervical collar. B, Child shown in an Ace wrap bandage.

fixation. In this younger age group, we suggest that circummandibular and piriform suspension wires, in addition to arch bars, be placed for added maintenance of IMF.⁵⁵

When the surgeon is treating jaw fractures, occlusal relationships are of the utmost importance. If available, every effort should be made to obtain up-to-date preinjury models to make occlusal splints. Alternatively, preoperative impressions can be taken of the child's injured jaws, and these impressions can be used to create stone models that may be cut, manipulated, and mounted on an articulator. After the ideal occlusion is established with the models, a surgical splint is made and used intraoperatively to guide the surgeon.

Treatment of pediatric mandibular fractures should be tailored to address each region of the mandible specifically. The goals are the same as for adults: restore normal occlusion, ensure bony union, and avoid infection.¹⁹ Because the pediatric mandible is full of developing dental follicles, a conservative approach to the treatment of fractures is always indicated.⁵⁹ Minor malocclusions from fractures are often well tolerated in infants and young children, because children have a remarkable ability to remodel their fractures well, and an orthodontist may manipulate and correct minor occlusal discrepancies at a later date. Therefore, if a fracture creates minimal displacement and the occlusion is essentially normal, a conservative approach is warranted. This usually includes a soft diet, dental hygiene, and mandibular rest. Some type of external splint, such as a cervical collar or an Ace wrap applied in the craniocaudal direction, can also be used (Fig. 40-13).

For patients with displaced fractures and significant malocclusion, surgical intervention is indicated. The specific surgical intervention depends on the fracture pattern. For single fractures (subcondylar) in infants and young children, closed manipulation should be performed first, and if normal occlusion is obtained, a course of MMF or functional elastic therapy can be used.⁶² If combination fractures are present (subcondylar and parasymphiseal) or if normal occlusion cannot be obtained, then open reduction and internal fixation is indicated. Internal fixation in infants and young children is a topic of controversy and should be minimized if at all possible. Usually an inferior border wire is preferable to metallic plate fixation (Fig. 40-14); however, resorbable miniplate fixation has gained favor when internal fixation is warranted. As discussed previously, arch bars often can be challenging to place in a pediatric patient, and alternative forms of MMF can be used (see Fig. 40-12). For older children who no longer have mixed dentition, routine

Fig. 40-14 Left-sided inferior mandibular border wire fixation of left-sided sagittal body fracture.

principles and techniques of mandibular fracture treatment apply. Many surgeons consider it appropriate to remove all nonresorbable fixation after fracture healing in growing children.

Condylar Fractures

The condylar head is considered a growth center of the pediatric mandible, and in infants and young children they are nothing more than “vascular bony sponges.”⁶³ Any injury that interrupts the blood supply and alters the morphologic structure can easily result in TMJ ankylosis and subsequent alteration of mandibular growth. The vast majority of condylar head or neck fractures in infants and young children should be treated conservatively; however, the specific treatment for a condylar fracture depends on the location of injury. Intracapsular condylar head injuries should be treated with a soft diet, gentle mobilization, and physical therapy, because the risk of ankylosis is significant with immobilization. When condylar head injuries occur in combination with other mandibular fractures, it may be an indication for open reduction and internal fixation of the other fractures so that immediate range-of-motion therapy and physical therapy may be started. Chewing gum can be a powerful tool for TMJ mobilization, along with other devices, such as a TheraBite (Atos Medical AB) to encourage mouth opening. The indications for opening a child's TMJ are few, and they include a foreign body in the joint or an inability to range the joint into occlusion. A displaced condyle in the middle cranial fossa is an extremely rare occurrence.³

Subcondylar Fractures

Most condylar neck fractures in infants and young children are treated with closed reduction and a short course of functional elastic therapy. Arch bars can be placed, and often a single contralateral elastic is all that is required. Subcondylar fractures in children are frequently greenstick, incomplete fractures that remodel well when treated conservatively with a soft diet and careful monitoring. If injuries are bilateral or there is a loss of ramus height resulting in an anterior open bite, closed reduction and external fixation with a short course of MMF (2 to 3 weeks) may be indicated. In adolescents, bilateral condylar neck fractures resulting in an anterior open bite may be an indication for open reduction and internal fixation of the condylar neck in the hands of those comfortable with that approach.

Body and Angle Fractures

When body and angle fractures are significantly displaced and/or associated with condylar head or neck fractures, open reduction and internal fixation (ORIF) is indicated. Often these fractures are sagittal and longitudinal. Whenever possible, intraoral incisions should be used for open treatment of pediatric mandible fractures. A transbuccal approach can be challenging and may

Fig. 40-15 A, Bilateral mandibular fracture in a 3-year-old boy. B, Axial CT scan showing bilateral sagittal mandible body fractures. C, Coronal CT scan of left condylar head fracture. D, Immediate postoperative axial CT scan of reduced mandibular body fractures with bilateral inferior border wire fixation. E, Six-month postoperative three-dimensional CT scan demonstrating normal mandibular morphologic structure. F, One-year follow-up with normal age-appropriate occlusion. G, One-year follow-up with normal maximal incisor opening.

result in inadequate reduction. When the surgeon is approaching the symphyseal region, care must be taken to leave a cuff of mentalis muscle on the mandible for resuspension to avoid the postoperative “witch’s chin” deformity. The mental nerve must be visualized to avoid injury and postoperative anesthesia. During open reduction, soft callous is gently curetted from the fracture site; the surgeon must be aware of developing tooth follicles and nerves.

Treatment of symphyseal or parasymphyseal fractures may require wiring of the mandibular border and dental bridle wires to adequately reduce and fix the fracture (Fig. 40-15). This fixa-

Fig. 40-16 Inferior mandibular border miniplate fixation.

tion technique usually treats the fracture adequately if a short course of MMF is also used, and it theoretically poses fewer disturbances to subsequent growth and development. If required or if MMF cannot be used, further fixation can be obtained with an inferiorly placed resorbable or metallic miniplate with screws placed monocortically and “aimed” away from developing tooth buds (Fig. 40-16). If metallic plates and screws are used, it is often recommended that they be removed after there is evidence of bony healing to prevent potential growth disturbances.⁵⁹

Alveolar Fractures

Treatment of alveolar fractures requires reduction of the dentoalveolar segment, fixation with wires or arch bars, and/or dental splinting with acrylic splints. This provides stabilization with little to no discomfort and, for older and cooperative children, can occasionally be done in an office setting. Postoperatively, dental hygiene and a soft diet are prescribed. Any minor occlusal malalignment can be addressed orthodontically after the fracture is completely healed. Close dental follow-up is encouraged.

Panfacial Fractures

Panfacial fractures, by definition, involve the upper, middle, and lower craniofacial skeleton. This fracture pattern is exceedingly rare in children. When children have panfacial fractures, they are usually associated with multiorgan injuries that make the management of these fractures challenging. Multiple schools of thought regarding the sequence of fracture repair have been proposed by different authors, and multiple approaches are often used to address the frontal region, upper midface, lower midface, occlusion, and basal mandibular area.⁶⁴ These include coronal, lower eyelid/transconjunctival, upper gingivobuccal sulcus, lower gingivobuccal sulcus, and preauricular-retromandibular incisions. The general goal is to reduce facial fractures to the skull base with an “outside-in” approach. This includes reducing the naso-orbital-ethmoid fracture to the nasion, the mandibular fracture to the glenoid fossa and TMJ, the zygomatic arch fracture to the temporal bone, and the zygomaticomaxillary complex fracture to the greater wing of the sphenoid and at the zygomaticofrontal suture. Our preferred sequence for pediatric panfacial fractures starts with direct reduction and fixation of palatal fractures and establishment of

an anatomic upper dental arch. This is followed by addressing subcondylar fractures, which establishes posterior mandibular height and reduces the mandible to the glenoid fossa-TMJ-skull base. After this, MMF is established and mandibular body fractures are fixated to establish lower facial width and occlusion. Next, the zygomaticomaxillary fractures are addressed. The zygomatic arch is reduced to the temporal skull base to establish anteroposterior projection of the face. The zygoma is reduced to the greater wing of the sphenoid-skull base and at the zygomaticofrontal suture. The nasoorbital-ethmoid fracture and central fragment are then reduced to the nasion. Reduction and fixation of the inferior orbital rim and LeFort buttresses follow.

Finally, orbital reconstructions are performed, which complete the panfacial fracture. It is important to develop a comprehensive treatment plan before surgery. This often includes coordination with the neurosurgery department for transcranial access, obtaining preoperative models for fabricating occlusal splints, and arranging with other surgical specialties and pediatric anesthesia to maximize the resuscitation of the patient before the prolonged surgery he or she may need to endure.

POSTOPERATIVE CARE

The immediate postoperative period may be exceedingly stressful for pediatric patients who undergo surgical treatment of facial fractures. This is especially true when IMF is involved. Parental presence and constant reassurance are essential parts of postoperative care. Surgically, two areas need special attention. First, the airway needs to be protected. This requires experience in the care of these patients to know when a surgical airway is required, and the decision should be made before fixation of the fractures. Second, in patients with fractures involving the orbit, thorough serial ophthalmologic examinations should be performed. Any signs of superior orbital fissure syndrome or orbital apex syndrome must be addressed immediately.

Antibiotics are not essential but should be used when specifically indicated. When bone grafts or hardware are used during the fixation of facial fractures, we advocate a short 3- to 5-day course of antibiotics. Antibiotics are also indicated when there is salivary contamination of the fractures or when the frontal sinus and intracranial space are involved. Careful wound care and oral hygiene are also very important. Our protocol includes antibiotic mouthwash every 4 hours in the immediate postoperative period and antibiotic ointment on all skin incisions.

The role of parenteral steroids remains controversial. Their use is considered most beneficial to decrease swelling in the airway and posterior orbit. A single intravenous dose of 0.5 to 1.0 mg/kg of dexamethasone is usually given.⁶⁵ Repeating and/or tapering additional doses is often considered. Higher doses may be required for optic neuropathy, and the guidance of a pediatric ophthalmologist is recommended. The potential risks associated with steroid use include postoperative infection, aseptic necrosis of the hip, and adrenal insufficiency, all of which are rare.

Routine postoperative CT scans are not always indicated; however, they are invaluable to evaluate reduction and fracture alignment and to document postsurgical treatment. In our opinion, these studies remain the most valuable learning tool for surgeons who have limited experience with surgical management of pediatric facial fractures. All children who have sustained facial fractures require annual follow-up during the period of growth and development of their craniofacial skeleton. Annual physical examination and assessment by a craniofacial surgeon and orthodontist are suggested. Yearly cephalograms and Panorex radiographs, along with dental impressions and standardized photographs, are obtained to document and track facial growth and development. We cannot stress enough the importance of serial dental and facial photographs taken at standard settings. These annual photographs not only document the injury and wound healing but also show subtle soft tissue, skeletal, and dental changes that may or may not occur after fixation of facial fractures.

A coordinated team approach is recommended for the care of pediatric facial fracture patients, similar to the care for cleft and craniofacial patients. The team should include the craniofacial surgeon, pediatric neurosurgeons, pediatric orthodontists and dentists, a pediatric ophthalmologist, a social worker, and a pediatric developmental specialist/psychologist who will focus on the developmental and psychological impact of the injury.

POSTOPERATIVE COMPLICATIONS

Postoperative complications after the treatment of pediatric facial fractures can be divided into three categories: those that occur as a result of the injury, those that occur as a result of the treatment, and those that occur over time with altered growth and development.^{66,67} The most drastic immediate complication is compromise of vision. As previously noted, even though children suffer fewer facial fractures in general, when they do, there is a higher incidence of blindness compared with adults. It is imperative to have a pediatric ophthalmologist evaluate the patient preoperatively to document a baseline examination and diagnose any injury. A postoperative examination should also be completed. If vision deteriorates in the immediate postoperative period, timely surgical reexploration is warranted.

Infection can also occur in the immediate postoperative period but is very unlikely in healthy young patients. Infection is more concerning when hardware or bone grafts were used for reconstruction. Any early infection requires judicious use of culture-specific antibiotics, drainage, and irrigation. Infections in the oral cavity after open reduction and internal fixation with hardware exposure can often be treated with antibiotics and good oral hygiene without hardware removal. True infections elsewhere in the craniofacial skeleton are more concerning and may require washout and removal of hardware. Bone grafts rarely become infected, but if this occurs, the graft invariably requires removal. This usually creates significant defects that are cosmetically and functionally displeasing when the soft tissue envelope collapses and scars. These patients frequently require extensive secondary reconstruction with autologous split calvarial or rib grafts. It is prudent to perform a delayed reconstruction, allowing the infection to subside and avoiding further graft loss. Infection can also occur in the subacute setting, which is more common when

Fig. 40-17 A, An infected bone substitute extruding through the temporal wound. B, A three-dimensional CT scan showing the fractured, infected, and extruding bone substitute.

nonautologous materials are employed, such as those used for cranioplasty (Fig. 40-17). When these infections occur, all of the offending material must be removed, and a delayed secondary autologous reconstruction must be performed.

Late postoperative complications in children with craniofacial fractures include bony contour deformities (for example, saddlenose), ophthalmologic disturbances (for example, enophthalmos and orbital dystopia), orthognathic deformities (for example, malocclusion) (Fig. 40-18), and the rare “growing skull fracture.” It is not uncommon to have minor contour discrepancies after the initial treatment of craniofacial fractures when unpredictable growth and development follow. These deformities most often do not require significant surgical corrections. However, when major bony deformities develop, extensive reconstruction with autologous calvarial bone or rib grafts is usually required.

Postoperative ophthalmologic disturbances include orbital volume-related problems such as enophthalmos and orbital dystopia, as well as soft tissue and scarring problems, including ectropion and extraocular muscle dysfunction. The goal of reconstruction is to restore pretraumatic orbital volume and morphologic structure. When this restoration is inadequate or when bone grafts are absorbed and soft tissues atrophy, enophthalmos may occur. Characteristic areas of bony loss include the orbital floor and posteromedial and lateral orbital walls. The basis of secondary orbital volume restoration is purely anatomic. This begins with alignment of the lateral orbital wall (greater wing of the sphenoid), establishing the key landmark for reduction of all other components of the orbital fracture. Frequently the malaligned zygomaticomaxillary fracture must be reosteotomized to mobilize and reduce the fracture segment. Additional osteotomies may be required to restore natural anatomy. After these units are stabilized by miniplates, the floor and medial wall defects can be repaired. A coronal incision may be needed to approach the posterior aspect of the medial wall.

Fig. 40-18 A, Postoperative malocclusion and chin point deviation resulting from altered growth after open reduction and internal fixation with metallic hardware. B, Panorex radiograph revealing metallic fixation and mandibular asymmetry.

Posttraumatic exophthalmos rarely occurs. It is most likely caused by a superior orbital roof fracture and herniation of the brain into the bony orbit. This generally requires a coronal incision and frontal craniotomy to reduce the herniated brain and place a bone graft and pericranial flap to cover the defect. Exophthalmos can also occur with excess correction and reduction of orbital volume. In pediatric patients, a growing skull fracture can also occur after an orbital roof fracture, and this may cause pulsatile exophthalmos.

Secondary orthognathic deformities occur in recognized patterns after facial fracture with or without treatment.⁶⁸ An elongated face with an anterior open bite may occur after LeFort fractures that are inadequately reduced and the posterior maxilla is inferiorly and posteriorly displaced.¹ This pattern of malocclusion can also occur when posterior mandibular height is lost by improper fixation of mandibular fractures or when the condyles are not correctly seated into the fossa at the time of the repair. To correct an anterior open bite, the fracture pattern is re-created, and anatomic reduction is performed with IMF. A posterior maxillary crossbite can occur if the ipsilateral mandibular ramus or angle fracture is inadequately reduced. This often requires orthodontic treatment to correct and, if severe enough, secondary orthognathic surgery.

As previously discussed, the condyles in the mandibles of pediatric patients are growth centers. Therefore condylar injuries have the potential to disrupt bony growth, causing asymmetry and malocclusion. This most commonly presents as secondary asymmetrical mandibular retrognathism and a decreased maximal incisal opening, giving the patient an ipsilateral occlusal cant and a deviated dental midline. To correct this deformity, distraction osteogenesis can be performed; alternatively, orthognathic surgery can be done after skeletal growth has been completed. The typical orthognathic procedures used to correct this deformity are bilateral sagittal split osteotomies of the mandible with a possible combined LeFort I osteotomy with or without osseous genioplasty.

LONG-TERM RESULTS

Despite timely and adequate treatment of pediatric facial fractures, long-term results remain unpredictable. Growth and developmental disturbances may occur from (1) the fracture itself, (2) an open approach and periosteal undermining, (3) rigid fixation of the fracture, and (4) disruption of growth centers within the pediatric facial skeleton. Numerous reports have documented unpredictable growth patterns and delayed deformities in the pediatric population after facial trauma. For example, growth disturbances associated with nasal fractures occur from a suspected premature ossification of the septovomerine suture,² whereas some reports indicate that zygomatic fractures rarely incur any long-term consequences.¹⁰ Orbital fractures occurring before the age of 7 years have been noted to cause growth disturbances; however, orbital growth is often complete after 7 years of age, and fractures after this are rarely associated with abnormal development.¹⁰ Nasoorbital-ethmoid fractures are not common in children; however, when they occur, the disruption of facial growth centers can result in midface hypoplasia in both the vertical and anteroposterior directions.²

The literature lacks comprehensive long-term follow-up of pediatric patients with facial fractures. We are currently involved in establishing a multicenter pediatric facial trauma registry to document the long-term consequences of facial fractures on the pediatric population and have recently published our early follow-up of a cohort of 177 patients over 1 year.⁶⁷ In this study, we introduced a classification system for facial fracture–related adverse outcomes: type 1 adverse outcomes were directly related to the fracture; type 2 adverse outcomes were directly related to the treatment; and type 3 adverse outcomes were related to the interaction between the fracture, treatment, and patient growth. Factors associated with worse outcomes included multiple fractures and fractures that required operative intervention.

KEY POINTS

- Children are not small adults; in addition, 5-year-old patients are not treated the same as 10-year-old patients, and they are not treated the same as 15-year-old patients. Each pediatric patient and each fracture are treated uniquely, applying the principles discussed in this chapter.
- Whenever possible, consideration should be given to treating young patients conservatively.
- CT scans are necessary for adequate evaluation of pediatric patients with facial trauma.
- Whenever possible, absorbable hardware should be used to treat pediatric facial fractures. Caution should be exercised when the surgeon considers the use of nonautologous materials for the growing pediatric craniofacial skeleton.
- When treating pediatric patients with craniomaxillofacial fractures, the practitioner must educate the family on the unpredictable growth and development that may follow these injuries, and he or she should commit to the long-term, adequate follow-up that these patients require.

Congenital Hand Anomalies: Embryology and Classification

Aaron Corde Mason • Pundrique R. Sharma

The hand is a complex organ. It is integral to human social interactions, communication, and multiple daily functions. Because of this, developmental anomalies of the hand may significantly affect the life of a newborn infant. Parents are justifiably concerned and seek restoration of normal hand function for their children. Hand anomalies pose significant challenges for reconstructive surgeons. Although aesthetic restoration is ideal, the reestablishment of anatomic foundations for normal hand function in a timely manner is imperative to minimize delays in acquiring gross and fine motor skills during newborn development.

The various causes of congenital upper limb anomalies are beginning to be more fully understood. Many have a genetic basis, although environmental influences can lead to developmental miscues. Congenital anomalies of the upper limb affect 1 in approximately 600 live births.¹ Many anomalies are isolated, but a few are syndromically associated with other systemic anomalies.

The development of the upper extremity is complex, and multiple opportunities exist for genetic and environmental influences to alter its normal development. This has resulted in a host of identified anomalies that have been categorized based on their morphologic features. This gave rise to a classification system that had little to do with actual embryology. As our understanding of normal embryology advanced, new concepts were discovered and new classification systems arose. The intent of this chapter is to provide an overview of normal upper extremity and hand development and to introduce the congenital hand classification systems most used in practice.

UPPER EXTREMITY EMBRYOLOGY

In humans, evidence of upper limb development appears at 26 to 28 days' gestation with the emergence of the upper limb buds.^{1,2} Digits can be first recognized on days 41 to 43, and the process culminates by days 51 to 53 with five segregated digits. Developmental activities are genetically orchestrated during this period. Spatial coordination of activities in a three-dimensional fashion is important for normal limb development, and numerous signals control the organization of tissues along each of the three axes in a process known as *pattern formation*.^{3,4} The three axes are the proximodistal axis, the AP (craniocaudal) axis, and the dorsoventral axis (Fig. 41-1). Each is associated with specialized tissues and tissue factors that direct development in a specific fashion.

The Three Axes

Upper extremity development begins with the expression of *sonic hedgehog* (*SHH*) from the notochord,⁵ leading to the formation of a limb bud from locally proliferating mesodermal cells at the appropriate upper flank level (Fig. 41-2). The limb bud soon evolves with cartilage precursor cells in the center (the chondrogenic core), and other connective tissue cells (destined to be tendons and muscles) accrue peripherally. This aggregate of mesodermal cells leads to a bulging of the ectoderm at the junction of the ventral and dorsal ectoderm, known as the *apical ectodermal ridge* (AER). The cellular activity signals the coalescence of the AER from local ectoderm along the rim of the limb bud. The AER navigates the evolving limb along the proximodistal axis and is responsible for separating the webbed hand through interdigital apoptosis.³ Highly mitotic cells within the mesoderm beneath the AER, in an area known as the *progress zone*, contribute to the growth of the bud laterally and distally. As limb growth progresses distally, more proximal cells leave the progress zone for their final positions within the developing limb.⁶ Cellular differentiation occurs, with more proximal structures evolving toward humeral precursors, followed by radial, ulnar, carpal, and phalangeal precursors distally. At this stage, failure or loss of the AER leads to transverse growth arrest.

Members of the *fibroblast growth factor* (*FGF*) family are also involved in the development of the upper limb.^{1,5-7} *FGF10*, detectable in flank ectoderm before the AER evolves, is a prospective trigger for initial limb bud formation. The AER itself expresses three *FGFs* (*FGF2*, *FGF4*, and *FGF8*) that probably participate in the proximodistal development of the upper limb. Experimentally, the combination of *FGF1*, *FGF2*, and *FGF4* leads to the development of a normal limb, and their application ectopically leads to ectopic limb formation.⁸ The zone of polarizing activity (ZPA) controls the pattern formation of the evolving upper limb in the craniocaudal (radioulnar) axis.^{4,5,7,9} Located on the caudal (ulnar) margin of the growing limb bud, this region contains highly specialized mesenchyme that expresses the protein *SHH*, which is released in a graded fashion along the AP axis of the developing limb. The result is a gradient of *SHH*, which is higher on the caudal edge of the developing limb and causes ulnarization and absent in the cranial edge, allowing radial digits to form.^{7,9} In this model, cells "sense" their location along a gradient, as well as their future positional information. Another model, Turing's reaction-diffusion model, postulates that positional information is not solely the result of a given morphogen's concentration; it is also the result of interactions of different morphogens that can be mathematically described and may be of particular relevance to digital differentiation and development.^{7,10,11}

Not unexpectedly, the AER and ZPA are intricately codependent in the embryogenesis of the upper limb.^{3,4,6} The integrity of the AER is essential to maintain an operational ZPA. *FGF4* produced by the AER supports the ZPA and maintains its expression of the *SHH* protein, which

Fig. 41-1 The axes of tissue organization. An arm bud shows the three axes whose differential development leads to the evolution of the human hand.

Fig. 41-2 Hand development. **A**, In part because of the influence of *FGF10*, upper extremity development is first noted by the formation of a limb bud from local mesodermal cells on the lateral side of the embryo. **B**, The emergence of the apical ectodermal ridge (*AER*) guides development in a proximo-distal axis. The progress zone (*PZ*) is identified behind the *AER*. The localized zone of polarizing activity (*ZPA*) forms, guiding development of the limb in the AP or radioulnar axis. **C**, As development continues, the limb evolves along all three axes as the various zones of activity work in concert. **D**, Under the guidance of the *wingless-type (Wnt)* signaling center, the limb differentiates in the dorsoventral axis. Ultimately, the digits separate under the influence of the *AER*, resulting in the familiar form of a human arm and hand.

is an inducer of AER-secreted FGF4 through a positive-feedback loop. Thus growth is exquisitely regulated in both the proximodistal and craniocaudal axes.

The dorsoventral axis is controlled in part by yet another set of genes located in the *Wnt* signaling center.^{1,3,4,6} The *Wnt7A* gene, expressed specifically in the dorsal ectoderm, is thought to play a significant role in dorsoventral polarity of the limb. The dorsal ectoderm where *Wnt7A* is expressed maintains the expression of *SHH*, thus integrating with the other two axes in the three-dimensional development of the upper limb.

TISSUE-SPECIFIC DEVELOPMENT OF THE UPPER LIMB

The upper extremity comprises multiple tissues, including bone, cartilage, muscle, tendon, vessels, nerves, and integument. Musculoskeletal development begins at the core of the limb bud. The chondrogenic core cells first differentiate into either chondrocytes or osteoblasts. Chondrification of the upper limb advances in a proximal to distal direction, beginning with the humerus and ending with the proximal parts of the distal phalanges. Important participants in this process include members of the sex determining region Y box (SOX) transcription factor group, the transforming growth factor beta (TGF-beta) superfamily, the FGF family, and the SHH protein. Joint development is the result of repression of chondrogenesis at specified joint sites.⁵ One of the proteins thought to be extremely important and upregulated at sites of joint development is Wnt14.¹² The muscles of the upper limb are identified in the embryo by week 7 of development. Paralleling skeletal development, proximal muscles evolve before more distal muscle groups, and superficial muscles develop before deeper muscles develop. Innervation of the developing muscles similarly begins at the limb bud and progresses distally. The vascular supply to the evolving limb begins as a series of capillary networks. The first vessel that appears is a marginal vein on the ulnar side of the developing limb. It is preserved as the subclavian-basilic system. The subclavian-brachial artery is the first artery to appear. It ultimately gives rise to the median artery, which initially supplies the hand. Although the ulnar artery appears before the radial artery, both finally lend vascular inflow to the hand as the median artery regresses.

MOLECULAR GENETICS OF CONGENITAL HAND ANOMALIES

Recent advances in molecular genetics have increased our understanding of the mechanisms involved with the organization and development of the upper extremity and of the genetic causes of some hand anomalies. On a molecular level, upper limb development occurs in a series of well-orchestrated biochemical steps. A cell produces and secretes a protein that binds a designated receptor on a target cell. The protein-receptor bond triggers changes within the target cell, resulting in specific transcription factors binding to DNA in the nucleus of the target cell. This leads to the expression of new target genes. When these sequences of events occur as planned, they culminate in the spatial development of the upper limb and hand.¹³

Several genes are involved in the normal development of the upper limb, and many are beginning to be identified. Mutations in many of the genes are associated with specified hand anomalies. Genes involved in preaxial polydactyly, split hand, and brachydactyly type C have been mapped to chromosomes, and the first human gene mutation associated with a hand anomaly is the *homeobox D13 (HOXD13)* gene mutation.^{1,14} As our understanding of hand development at the molecular level expands, more anomalies will be described genetically.

An introduction to the genetics of hand development and the anomalies that occur when the process diverges from the expected requires a cursory understanding of the homeobox genes.^{1,3,14} *HOX* genes are intimately involved in embryogenesis and are highly conserved across species. They direct cells within the early embryo into fields, each with the potential to become differ-

ent tissues and organs. All vertebrates have *HOX* genes organized into four complexes (*HOXA*, *HOXB*, *HOXC*, and *HOXD*), and each complex is located on a separate chromosome. The name *HOX* identifies a gene from one of the homeobox gene clusters. During upper limb development, the *HOX* genes play an important role in the interactions between the AER and the underlying PZ. As the limb evolves, various combinations of the *HOX* proteins are expressed at specific times and positions within the PZ. For example, the expression of the *HOXA* and *HOXD* is regulated in phases associated with the patterning of the segments of the upper limb: the arm (the embryologic name is *stylopod*), forearm (*zeugopod*), wrist (*mesopod*), and hand (*autopod*).^{5,7} In this way, the cellular milieu is directed proximodistally to evolve into the upper arm, lower arm, and hand structures. *HOXD* gene expression patterns in the hand result in five fields that lead to the morphologically distinct five recognized digits. For this reason, hand anomalies, such as syndactyly and polydactyly, may originate in the *HOXD* cluster.

Synpolydactyly is a congenital hand anomaly linked to a *HOXD* gene.¹⁴ Identified as syndactyly of the third and fourth fingers and the fourth and fifth toes in association with polydactyly of the same fingers and toes, synpolydactyly typically has an autosomal dominant inheritance pattern. The responsible gene was initially mapped to chromosome 2q31, and further work identified that the specific mutation was an expansion of a polyalanine sequence in the *HOXD13* gene, the first identified in humans. Similarly, the precise genetic causes of preaxial polydactyly, split-hand/split-foot malformation, and brachydactyly type C are beginning to be understood, each of which is mapped to chromosomes 7, 10, and 12, respectively. Current efforts are focused on identifying the specific mutations responsible for their occurrences.

As with all facets of medicine, advances in molecular genetics are just beginning to result in findings to complement our understanding of various anomalies and disease states. Our understanding of hand development and the anomalies that may occur will only be augmented as more data become available.

CLASSIFICATION SYSTEMS FOR CONGENITAL HAND ANOMALIES

Classification systems for pathologies and anomalies are essential. They provide a way for professionals to comprehensibly communicate with each other using consistent nomenclature to group similar pathologies together and to separate distinct pathologies, often indicating etiologic factors, management, and prognosis. Ideally, classification systems stratify conditions according to severity and the possible available treatments. In theory, they should guide users to an understanding of the nature of the disease process in question. However, because classifications are artificial and based only on the understanding of the pathology at a given point in time, they are inevitably subject to inaccuracies, changes in our knowledge, new understandings, and the variations of contemporary and future attitudes, only some of which will stand.

The history of the classification of congenital hand anomalies dates to the 1830s and the work of the French comparative anatomist Isidore Saint-Hilaire,¹⁵ who introduced names such as *phocomele*, literally meaning *seal hand*. After this publication, many other classification systems were developed. In 1974 Kelikian¹⁶ further described the timeline of congenital hand classification systems. The most commonly used and well-known classification system may be the one that Swanson and colleagues¹⁷ proposed in 1968 and that the International Federation of Societies for Surgery of the Hand subsequently revised and adopted.¹⁸ The classification contains seven categories (Box 41-1). The first two categories (failure of formation and failure of differentiation) contain the conceptual seeds for describing the causes of the nature of the malformations; however, the next five categories (duplication, overgrowth, undergrowth, constriction band syndromes, and generalized anomalies and syndromes) are essentially descriptive.

Failure of parts to form includes transverse and longitudinal deficiencies of the upper extremity. They are discussed in Chapter 42. Congenital transverse deficiencies are usually isolated,

Box 41-1 Swanson Classification of Congenital Hand Anomalies

- I. Failure of formation of parts

 - B. Macrodactyly
- V. Undergrowth
- VI. Congenital constriction band syndrome
- VII. Generalized skeletal anomalies

sporadic, and unilateral and are identified according to the last remaining bone segment. The most common congenital transverse deficiency is a short below-elbow amputation. Longitudinal deficiencies may include radial, ulnar, or central deficiencies. Radial deficiencies affect the cranial, preaxial border of the arm and are often associated with systemic conditions, including Holt-Oram syndrome, thrombocytopenia-absent radius (TAR) syndrome, Fanconi anemia, and the VACTERL (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities) association. The seriousness of the radial defect ranges from a minimally affected thumb to the absence of the thumb, carpus, and radius¹⁹ (Table 41-1). Ulnar deficiencies are far less common than their radial counterparts and affect the postaxial side of the limb. Although they may be associated with other musculoskeletal anomalies, they are not typically associated with systemic syndromes.

In 1993 Bayne²⁰ described the classification system that is probably most commonly used. Similar to the classification for radial dysplasia, it categorizes dysplasia according to the severity of the abnormality of the ulna (Box 41-2). According to findings at the thumb and first web space, ulnar deficiencies are further classified into four groups, ranging from a normal thumb and web space to an absent thumb²¹ (Table 41-2). Finally, central hand deficiencies, or a cleft hand, result from the longitudinal loss of the index, long, and/or ring rays of the hand.

Syndactyly is an abnormal connection between adjacent digits and is the most common congenital hand anomaly associated with failure of differentiation. The connection may involve the entire length of the digit (complete), or it may end proximal to the fingertip (incomplete) (Chapter 44). Furthermore, only skin and fibrous tissue may be involved (simple), or adjacent phalanges may be attached (complex). Congenital syndactyly occurs in 2 of every 10,000 live births,²² tends

Table 41-1 Classification of Radial Deficiency

Type	Thumb Anomaly	Carpal Anomaly	Distal Part of Radius	Proximal Part of Radius
N	Abs/hypo	Normal	Normal	Normal
0	Abs/hypo	Abs/hypo	Normal	Normal, radioulnar syndrome or radial head dislocation
1	Abs/hypo	Abs/hypo	>2 mm shorter than ulna	Normal, radioulnar syndrome or radial head dislocation
2	Abs/hypo	Abs/hypo	Hypoplasia	Hypoplasia
3	Abs/hypo	Abs/hypo	Absence of physis	Variable hypoplasia
4	Abs/hypo	Abs/hypo	Absence	Absence

Abs/hypo, Absent/hypoplastic.

Box 41-2 Classification of Ulnar Deficiency in the Forearm

1. Ulnar deviation of the wrist without hypoplasia of the ulna
2. Hypoplasia of the ulna
3. Partial absence of the ulna with radial bowing
4. Total absence of the ulna

Table 41-2 Classification of Ulnar Deficiency According to Abnormality of First Web Space

Type	Grade	Characteristics
A	Normal	Normal web space and thumb
B	Mild	Mild deficiency of first web space and mild thumb hypoplasia Intact opposition and extrinsic muscle function
C	Moderate-severe	Moderate-severe deficiency of first web space and thumb hypoplasia with malrotation, loss of opposition, and extrinsic dysfunction
D	Absent	Absence of thumb

to be familial, and may be isolated or part of more systemic syndromes, such as Apert syndactyly, which is discussed in Chapter 45.

Duplications include polydactyly, thumb duplications, triphalangism, and mirror hand are described in Chapter 46. Polydactyly occurs on both the preaxial and postaxial sides of the hand. Preaxial polydactyly (radial) is more common in whites, whereas postaxial polydactyly (ulnar) has a higher incidence in blacks. Postaxial polydactyly is often an autosomal dominant trait. In both preaxial and postaxial polydactyly, the extra digit may be a rudimentary element of soft tissue, or it may be nearly completely formed, including bones. Thumb duplications, more common in whites, are usually unilateral, sporadic, and isolated, and the classification is presented later in the chapter.

Macrodactyly, or overgrowth, is usually an isolated anomaly, but it is sometimes associated with other conditions such as neurofibromatosis or Klippel-Trenaunay syndrome. It is discussed in detail in Chapter 47.

Thumb hypoplasia is the most common form of undergrowth in developing hands (see Chapter 48). Blauth²³ has proposed a distinct and useful classification that is discussed in the section Classification of Specific Anomalies later in the chapter.

Congenital constriction band syndrome describes the demise of distal developing hand structures because of tourniquet constriction by amniotic bands in utero. Parts of the upper extremity, most often digits, are amputated. The level of amputation directs intervention and therapy, which may range from physical therapy to surgical intervention to optimize hand function. The classification, causes, and management are discussed in Chapter 49.

Evolution of the New Oberg, Manske, and Tonkin Classification System

With an increased understanding of the embryologic processes involved in upper extremity development, a renewed interest in classifying congenital anomalies arose. This is quite logical, because, at the time of inception of the Swanson classification,¹⁸ relatively little was known about the developmental biology of the patterning of the upper limb; thus it did not necessarily correlate well with the embryologic mechanisms leading to the disorders. Furthermore, the classification system provided no information on severity, prognosis, and management; it combined disorders that might intuitively be considered disparate; and it separated disorders that might otherwise be considered similar. However, it accomplished the difficult task of encompassing almost the entire, broad range of congenital hand anomalies. Because of its relatively simple nature, it was easy to use and apply practically. As a result, it was widely adopted as the classification of choice to describe congenital hand anomalies.

After the Swanson/IFSSH classification was generally accepted (see Box 41-1), understanding of the embryology underlying limb development and abnormal development evolved significantly, in part because the developing limb bud was the organ of choice for studying developmental patterning in general. In 1969 Wolpert²⁴ proposed the French Flag model of embryonic development, in which positional patterning information is determined by molecular gradients. Seminal work by Saunders,²⁵ Tickle,^{26,27} and others in the late sixties and later described the concept of the vertebrate limb patterned in three axes. This work was vital to our conceptual understanding of how the limb is patterned and therefore how congenital anomalies arise. Despite these dramatic scientific changes in our understanding and the development of other classification modifications,²⁸ the congenital hand surgery community continued to primarily use the clinical nomenclature of the Swanson/IFSSH classification for more than 3 decades.¹⁷

Recently, however, the developmental biologist Oberg, the late Paul Manske, and the Australian surgeon Tonkin (OMT)²⁹ reconsidered how we classify upper limb anomalies. They aimed to produce a comprehensive classification of upper limb anomalies that included our current understanding and nomenclature of the developmental biology of the growing limb bud³⁰ (Box 41-3). The OMT classification system²⁹ was proposed in 2010 and revised in 2013.³¹ Although it may at first seem very complicated, it is essentially divided into four major groups. The first group, the malformations, includes anomalies in formation and differentiation in which abnormal development has occurred along one or more of the three axes of development (for example, radial longitudinal deficiency). The second group, the deformations, describes an alteration or distortion to a limb or limb element that has already formed, such as those that occur with constriction bands. The third group includes dysplasias, in which “axial” and positional development is normal, but tissue growth is abnormal (hypertrophy, vascular anomalies, and other congenital tumorous conditions). The fourth group describes limb abnormalities associated with syndromes, such as Apert syndrome.

Box 41-3 Extended Version of the Oberg, Manske, and Tonkin Classification and Proposed Additions

- I. Malformations
 - A. Failure of axis formation/differentiation—entire upper limb
 1. Proximodistal axis
 - a. Brachymelia
 - i. Brachymelia with brachydactyly
 - ii. Symbrachydactyly
 - iii. Transverse deficiency
 - (a) Amelia
 - (b) Clavicle

 - d. Epiphyseal abnormalities
- IV. Syndromes
 - A. Specified
 1. Apert
 2. Arthrogryposis
 3. Baller-Gerold
 4. Bardet-Biedl

The IFSSH has reviewed the OMT classification system and recently decided to support its use instead of the previous system (the Swanson/IFSSH classification system).³² They claimed that the new system not only comprehensively covers the range of congenital malformations, but also accounts for the nature of the underlying developmental pathology in more detail than the previous classification system. Table 41-3 provides a comparison of these two classification systems. Recently, other studies have compared the new system with the previous one.^{30,31,33} The results supported the IFSSH findings—the OMT system comprehensively and, of most importance, dependably (that is, with reference to interobserver and intraobserver consistency) covers the range of congenital hand malformations. The authors cautioned that the OMT classification had not yet gained as widespread a popularity as its predecessor, perhaps because of the simplicity and entrenched popularity of the older classification. They explained that although the new classification system encompasses the spectrum of congenital upper limb conditions comprehensively, so does the Swanson/IFSSH system,³² but without the same degree of reference to the underpinning mechanisms. Neither classification system describes (or claims to describe) severity (or prognosis) or management. Both classifications present disorders that are not conveniently assigned to only one group or another; for example, Apert hand could be considered a failure of differentiation (Swanson classification), a malformation (OMT classification), and a syndromic hand.

How the OMT classification system stands the test of time, which its predecessor did remarkably well, will depend on how well it organically incorporates new disorders and further advances

Table 41-3 Comparison of the Swanson/IFSSH and Oberg, Manske, and Tonkin Classifications

Swanson/IFSSH Classification	Oberg, Manske, and Tonkin Classification

in developmental biology, and perhaps (of even more importance) how easily current and future pediatric upper limb surgeons will manage to apply it in daily practice.

Classification of Specific Anomalies

A review of the literature relating to almost any hand disorder (congenital, acquired, pediatric, and adult) will reveal multiple classification systems—too many to discuss in a single chapter. However, some systems are of special interest because of the relatively common nature of the conditions they describe and because of their longevity. These are briefly mentioned in the following sections.

Thumb Duplication

Wassel³⁴ described the most commonly used classification of thumb duplication while he worked as Adrian Flatt's fellow (1969). It describes the proximodistal skeletal level of the duplication (I through VI), and VII refers to a triphalangeal thumb³⁴ (Fig. 41-3). It is easy to use because of its simplicity and correlation with the necessary surgical management. However, because of the immaturity of the bones, the true skeletal nature of the duplication often cannot be determined based on radiographic and clinical assessments but only intraoperatively. The word *duplication* may be misleading in that both of the “duplicated” ray digits are invariably evidently smaller and more hypoplastic than a normal thumb (in contrast to ulnar duplication/polydactyly) and are perhaps more akin to a split or bifid thumb.

Ulnar Duplication and Polydactyly

In 1963 Stelling³⁵ and Duran et al³⁶ presented one of the most often used systems for classifying ulnar polydactyly (Table 41-4). It is easy to use. However, despite including most scenarios, it does not account for the nuances of many variations, such as the details of the relationship between the accessory and the main digit. As a result, a variety of other classification systems were proposed³⁶ (see Table 41-4).

Syndactyly

Temtamy and McKusick³⁷ published a classification for syndactyly that identified the affected web space (usually the third). Swanson¹⁸ presented a descriptive classification of syndactyly based on

Fig. 41-3 The Wassel classification of thumb duplication.

severity (simple, with skin alone, and complicated, with the involvement of other tissues). Variations were published. Currently, the most commonly used adaptation of this classification for syndactyly describes the pathology as complete (in a proximodistal direction), incomplete, simple (not involving bone), complex (involving bone), or complicated (an abnormal arrangement of structures beyond fusion).^{38,39}

Table 41-4 Previously Reported Classification Systems for Ulnar Polydactyly and the Proposed Classification System in the Current Study

Temtamy-McKusick Classification*	Stelling Classification†	Rayan-Frey Classification‡	Al-Qattan Modification of Rayan-Frey Classification§	Pritsch et al Classification for Type A Ulnar Polydactyly¶	Duran et al Current Classification
Type A: A well-formed extra digit with an articulation	Type I: Soft tissue only	Type I: A soft tissue nubbin	Type I: A small, soft tissue nubbin with no bone or nail	Type I: A fully developed sixth ray that articulates separately with carpals	Type I (simple type): A skin nub similar to a verruca that does not contain bone and nail or a nonfunctional digit that contains bone or nail, or both, and a small pedicle that does not articulate with the metacarpal
Type B: A poorly formed extra digit connected to the hand by a skin bridge	Type II: Duplication of phalanges	Type II: A pedunculated, nonfunctioning digit	Type II: A pedunculated, nonfunctioning digit attached to the hand by a narrow (<3 mm) pedicle (type IIA) or by a wider pedicle (type IIB)	Type II: An extra digit on the lateral side of the fifth digit with an intercalated distal metacarpal remnant	Type II (hypoplastic type): a hypoplastic proximal phalanx
	Type III: Complete duplication of the phalanges and metacarpal	Type III: A well-formed, functioning digit articulating with a bifid fifth metacarpal head or fused to the fifth metacarpal at a right angle or hypoplastic absence of the proximal phalanx	Type IIIA: A well-formed, functioning digit articulating with a bifid metacarpal head or a partially duplicated fifth metacarpal Type IIIB: A well-formed, functioning digit with its proximal phalanx fused to the fifth metacarpal (type IIIB)	Type III: A supernumerary digit arising from a hypoplastic sixth metacarpal or fused to a fifth metacarpal	Type III (malformations at the proximal phalanx level, two subdivisions): Type IIIA—a bifid proximal phalanx Type IIIB—a duplicated proximal phalanx

*Does not include fusion between the proximal phalanx and metacarpal, triplication, polysyndactyly, or hypoplastic proximal phalanx.

†Does not include fusion between the proximal phalanx and metacarpal; a bifid metacarpal head, metacarpal remnant, or bifid metacarpal shaft; triplication; or polysyndactyly.

‡Does not include duplications of the proximal phalanx or triplication of the little finger.

§Does not include duplications of the proximal phalanx.

¶Does not include triplication or polysyndactyly.

**Fig. 41-4** Classification of congenital thumb hypoplasia.

Thumb Hypoplasia

Blauth²³ described the classic classification system, in which thumb hypoplasia is categorized according to severity. Various modifications have been developed⁴⁰ (Fig. 41-4). Manske and McCarroll⁴¹ introduced a division in type 3, which may be the key modification. Type 3A is a thumb with a functioning carpometacarpal joint, and type 3B does not have a functioning carpo-

metacarpal joint. The significance of this division is that types 1 to 3A describe thumbs that can probably be reconstructed to a useful digit, whereas types 3B to 5 cannot. David Chiu⁴² recently presented the possibility of reconstructing type 3B and those even more severe using toe-to-hand transfer and carpometacarpal joint reconstruction using a tendon coil. Long-term outcomes have not been reported.

CONCLUSION

The spectrum of congenital hand anomalies is interesting and varied. Our understanding of the causes of these conditions continues to grow. Surgically, the challenges of creating an organ as intricately engineered as the hand is daunting but nonetheless rewarding as we strive to deliver a functional hand to an infant born with one of these anomalies. Central to this endeavour is an understanding of hand embryology. This is needed to optimize strategies for therapy and intervention and to classify this diverse group to facilitate communication between health care professionals working with children with congenital upper limb anomalies.

KEY POINTS

- The upper limb develops from day 26 (limb buds emerge) to day 53 (five digits are formed) of gestation.
- Homeobox gene expression determines the craniocaudal position of limb development.
- Limb buds develop and differentiate in three axes: proximodistal, dorsopalmar, and radioulnar. Perturbations in this development can lead to congenital anomalies.
- The IFSSH currently recommends the OMT classification,²⁹ which is based on the developmental anomaly responsible for the abnormality (malformations, deformations, dysplasias, and syndromic). The previous IFSSH classification (proposed by Swanson and colleagues¹⁷ and still commonly used) is primarily based on the morphology of the anomaly.
- Both systems should be appreciated, including their evolution.
- Specific congenital anomalies have their own classifications. Many are graded according to severity and provide indications for treatment options.

Congenital Hand Anomalies: Failure of Formation

*Kristen M. Davidge • Emily S. Ho • Gregory H. Borschel
Howard M. Clarke*

he group of conditions classified based on the failure of formation of parts is characterized by complete or partial arrest in development of a limb.¹ These conditions are further classified as those with transverse arrest and those with longitudinal arrest. Transverse arrest refers to conditions with terminal transverse deficiency usually presenting with a stump at the level of amputation (Fig. 42-1). All other skeletal limb deficiencies are longitudinal (Fig. 42-2).

In several studies evaluating the frequency of failure of formation of the upper extremity, estimates range from 10.9% to 17.6%.²⁻⁵ Giele et al² conducted a survey in Western Australia of data over an 11-year span and concluded that failure of formation of parts accounted for 15% of all congenital upper extremity anomalies. A similar study in Sweden documented that failure of formation occurred in 103 of 585 congenital upper limb anomalies (17.6%) in children born between 1997 and 2007.⁵

Fig. 42-1 **A**, This 13-month-old child has transverse arrest at the level of the distal humerus. The nubbin on the anterior surface of the distal aspect of the limb may represent the remaining, undeveloped limb. **B**, The child is wearing a passive prosthesis on her left arm. The primary purpose of this prosthesis is to normalize the appearance of the limb. However, the device prohibits the child's sensation of the limb. **C**, With the prosthetic device removed, the child integrates her left arm for bilateral play. She uses the available range of motion (ROM) and sensory feedback on the affected side to assist the unaffected limb.

Fig. 42-2 This radiograph shows the upper extremity of an infant with unilateral absence of the ulna. This is classified as postaxial longitudinal arrest (or ulnar deficiency).

FUNCTIONAL EVALUATION

Functional evaluation of children with congenital hand anomalies not only involves a detailed musculoskeletal examination, but also a thorough evaluation of how they use their upper extremities in daily activities.⁶ A thorough functional evaluation is critical in making recommendations for nonsurgical and surgical treatment.

At the initial visit, the medical and family history should be documented. Concern about inheritance may warrant a referral to a genetics professional. A thorough musculoskeletal examination of both upper extremities is conducted, noting in detail the present and absent skeletal structures and active and passive ROM. The lower extremities are evaluated for associated anomalies. Caregivers are informed of the etiologic factors and prognosis of their child's condition. The family's general concerns regarding cosmesis and overall psychosocial response to the child's condition are noted.

Regular evaluation begins when children are 3 months of age and includes assessment of fine motor, bimanual skills and upper limb use in daily activities. This provides valuable information

for determining surgical management. Global development is evaluated during infancy to help caregivers have appropriate expectations for their child's development. Caregivers need reassurance of their child's ability to adapt and successfully achieve developmental milestones, despite the limb difference.

Children are evaluated when they are of preschool and school age to determine changes in ROM and performance in activities of daily living. Deficits in upper limb use or prehension in daily living, school, and/or leisure activities may provide indications for surgical or therapeutic reconstruction. Therapists can also provide input regarding adaptive techniques and aids to assist with daily activities. This is especially useful for patients who require assistance in adapting to a specific activity or sport. Routine evaluation is important, because functional demands change as patients mature.

Transverse Arrest

Transverse arrest is the congenital terminal amputation of a limb. It is classified according to the anatomic level where the limb terminates.^{1,7,8} The common levels of transverse arrest are the following⁶⁻⁸:

- Phalangeal
- Transmetacarpal
- Wrist
- Proximal forearm
- Midarm
- Shoulder

Amputation at the proximal forearm is most common.^{7,9,10}

Transverse arrest is usually unilateral^{7,11} and occurs more frequently on the left side.^{3,5,10} It is not usually associated with other malformations.¹¹ However, it has been confused with amniotic band syndrome.¹² The literature is varied regarding the incidence in males and females. Ogino et al³ reported no difference in incidence between gender. Birch-Jensen reported¹⁰ a female/male ratio of 3:2.

Epidemiology

Lamb et al¹³ conducted a survey of seven clinics internationally through the congenital malformations committee of the International Federation for Societies of the Surgery of the Hand. The extrapolated frequency of transverse arrest from these data was 1.5 in 100,000 live births. Birch-Jensen¹⁰ reported an incidence of 1 in 20,000 newborns for forearm arrest and 1 in 270,000 newborns for all transverse arrests. In another study, the incidence of transverse arrest was reported as 0.19 in 1000,¹⁴ accounting for 2.9% to 6.8%^{3-5,13} of children with congenital upper limb malformations.

A universal cause of congenital transverse arrest has not been identified.¹¹ Most cases are considered sporadic occurrences; however, the possible influence of teratogenic factors has not been ruled out.¹⁵ A positive family history has not been found.^{3,4} According to some authors, the mechanism of injury is linked to vascular injury in utero.^{16,17} Graham et al¹⁶ found that mechanical compression of the embryo at an early stage of development caused vascular disruption and ischemia, thereby arresting the development of the limb. Hoyme et al¹⁷ found evidence of vascular injury leading to ischemia in the developing limb. They reported that embolization from thrombi originating from the placenta caused occlusion in the brachial artery of the fetus.

Anatomy

Forearm amputation occurs most often in the proximal third of the forearm.¹⁰ The olecranon and trochlea are usually well developed; however, the development of the radial head varies.⁷ Subluxation of the proximal radioulnar joint and radial head dislocation are common.¹¹ The stump may have a variety of contours but is usually bulbous and well padded.^{8,9} Occasionally, vestigial nubbins with or without nail remnants are present at the end of the stump⁷⁻⁹ (see Fig. 42-1).

Patients with transverse amputation at the metacarpal or wrist levels may have motion at the radiocarpal joint if their extrinsic flexors and extensors of the forearm are well developed.¹¹ The remaining distal portion of the limb is often hypoplastic. Dimpling or retraction of tissue at the stump may indicate the presence of extrinsic flexor and extensor tendons; however, these structures are often hypoplastic.¹¹ Vestigial nubbins with or without nail remnants may be present.^{11,18}

Phalangeal amputations are rare⁷ and often associated with amniotic band syndrome^{11,12} (Fig. 42-3). If amniotic band syndrome is suspected, a thorough evaluation of all limbs should be conducted for evidence of constriction rings. Generally, all structures proximal to the level of the transverse arrest are normal, but osseous hypoplasia in the hand and forearm may occur.^{11,18}

Children with unilateral transverse arrest spontaneously and actively use their limb to explore and feel objects, because sensation is intact in the stump. Prehension is typically absent in the affected limb. However, many children use the limb to assist their dominant, unaffected limb for bilateral activities. For example, the affected limb is used to stabilize objects against the chest for manipulation with the unaffected hand. Some clinicians think that a passive upper extremity prosthesis (see Fig. 42-3) can assist in balance and gross motor development in infancy.¹⁹ Equalizing the limb length helps patients perform developmental skills¹⁹ such as creeping, propping in a prone position, and transitional movements from sitting to standing. We have observed these children achieve developmental milestones within an age-expected timeline without a passive prosthesis. Furthermore, families report that their children become frustrated with the passive prosthesis. We think this is at least in part from the inhibition of sensory exploration with the affected limb.

Evaluation

A child with transverse arrest should initially be seen within the first 3 months of birth for a functional assessment. Some parents are very keen to have vestigial nubbins removed to reduce the risk of accidental injury to these parts. We prefer to allow children to be involved in this decision at a later age. Some children seem to develop a fondness for their nubbins, whereas others find

Fig. 42-3 This 5-month-old infant has amniotic band syndrome affecting the digits in her right hand. Constriction bands are present around the proximal phalanx of her long and ring fingers. The distal and middle phalanges of the ring and little fingers are amputated. Digital amputation with evidence of constriction bands, as shown, is an indication of amniotic band syndrome as opposed to transverse arrest.

them inconvenient. Referral to an appropriate prosthetic facility can be initiated at this time. Although we have expressed some reluctance about early prosthesis use, referral to such facilities will provide parents with information about their child's present and future prosthetic options.

Nonoperative Management

Patients who have transverse arrest proximal to the forearm may be candidates for a prosthetic limb. Prosthetics are effective in providing a degree of prehension in the affected limb. However, young children may neglect their prosthesis because of the lack of sensory feedback and favor the sensate hand.²⁰ Visual cues and increased attentiveness are required of children who use a prosthesis.²¹

Shaperman et al²² surveyed data from 45 prosthesis clinics in North America regarding their clinical practice. The timing of the initial fitting of prosthetic devices was guided by the evaluation of the child's developmental signs such as evidence of independent sitting and exploration of the hand. The age at the initial fitting ranged from 2 months to 2 years. All clinics first introduced the children to passive prosthetic devices and then introduced an active device at an average age of 18 months (see Fig. 42-3). They found that a child's incorporation of a prosthetic device was not related to early fitting. Children with myoelectric prostheses participated in therapy programs to learn how to activate their terminal device.²³ As they matured, therapists assisted them and their family in using their myoelectric limb for specific activities in their daily living.²³ Children with short residual limbs often were unhappy with the distal weight of the prosthesis.²³

Amputations distal to the wrist may be fitted with a passive prosthetic hand or spatula (Fig. 42-4). Prosthetic hands are not functional devices, but they provide aesthetic benefit. A cosmetic hand is typically prescribed at adolescence for social functions.²¹ Spatula prosthetic devices are designed to allow children to oppose their hand against a hard surface for grasp.²⁴ These patients are not candidates for electronically powered prosthetic devices, because the amputation is too distal to support the mechanics of a myoelectric device.

Fig. 42-4 On the *left* is a spatula orthotic that can be used to facilitate prehension for a child with only one plane of movement. The spatula orthotic is secured to the child's forearm with Velcro straps. The child can press down on the surface of the spatula with their digits to hold small objects. In the *center* is an example of a silicone passive cosmetic prosthesis. On the *right* is a baseball glove fabricated to fit on a child's hypoplastic hand to facilitate participation in an activity of interest.

Operative Management

Operative options for managing transverse arrest are limited. We recommend removal of vestigial nubbins that interfere with normal activities. Ordinarily, this would be done once the child has expressed an interest in proceeding. However, an earlier procedure may be indicated if the nubbin causes a functional problem, such as recurrent bleeding with trauma.

The Krukenberg procedure is usually considered a reasonable option only in bilateral amputees (either congenital or acquired) who are also blind.²⁵ However, other authors have attempted to expand the indications for the procedure to include patients with intact sight, stating that the improvement in function outweighs the cosmetic trade-offs.^{26,27}

The procedure entails constructing a pincer grasp between the radius and ulna.²⁷ The pronator teres becomes the primary adductor of the radius. A cleft is created between the radius and ulna with dorsal and volar incisions, preserving full-thickness tissue on the tactile surfaces of the reconstruction. The flexor digitorum profundus and flexor pollicis longus muscle bellies are excised to debulk the stumps and to facilitate closure. The median and ulnar nerves are divided distal to the branches to the flexor digitorum superficialis and flexor carpi ulnaris. The flexor digitorum superficialis tendons, which help to motor the pincer grasp, are then evenly distributed between the radius and ulna and inserted into the bone. The tendons of the extensor digitorum communis are similarly distributed between the radius and the ulna, and the deep extensors are excised to facilitate closure. The interosseous membrane is then divided, opening the cleft between the radius and ulna as widely as possible. Split-thickness skin grafts are used as needed; only full-thickness skin should be used on the tactile surfaces.²⁶

Longitudinal Deficiency

Conditions classified as failure of formation with longitudinal deficiency are typically identified by the bones that are completely or partially absent.¹ They are classified as preaxial, central, postaxial, and intersegmental deficiencies.¹

The prevalence of longitudinal deficiencies is 4.6 in 10,000.¹³ Lamb et al¹³ and Ekblom et al⁵ reported an incidence of 12.5% and 13.8%, respectively, of total congenital upper limb malformations. Other studies have indicated lower incidences of 4.3% to 8%.^{3,4}

RADIAL RAY DEFICIENCY: PREAXIAL ANOMALY

Radial ray deficiency, also known as *radial club hand*, *radial hemimelia*, *radial dysplasia*, *radial aplasia*, *radial hypoplasia*, and *radial ray hypoplasia*,^{9,27} is characterized by shortening of the forearm and marked radial deviation of the hand at the wrist²⁸ (Fig. 42-5). The lack of radial support causes the hand and wrist to deviate toward the side of the deficiency.¹¹ The range of radial deficiency spans from minor abnormality of the thenar muscles to complete absence of all preaxial structures involving the upper arm and brachial plexus.¹¹

Riordan^{28a} classified radial ray deficiency into two main types of deformity: complete absence and partial absence of the radius. Bayne and Klug²⁹ have further classified this condition into four types²⁹ (Fig. 42-6 and Table 42-1). Type IV, complete absence of the radius, is most common. James et al³⁰ have described type 0, in which the radial carpus is hypoplastic and the wrist is deviated radially, but the radius itself is of normal length.

Fig. 42-5 A, This 2-year-old child has a typical presentation of a radial longitudinal deficiency type IV (see Table 42-1). She has marked radial deviation of the wrist on the forearm. (The elbow is held in extension in this image.) The residual ulna is shortened to approximately 60% on the unaffected side. This child also has a Blauth type IV hypoplastic thumb, otherwise known as a “pouce flottant” or floating thumb (see Chapter 43). B, As the child reaches for a small object, she widens the web space between her long and little fingers to prepare for grasp. The ulnar digits are preferred for prehension. C, The child is wearing a static low-temperature thermoplastic orthotic that centralizes the wrist over the ulna. For patients who may undergo centralization surgery, static splints can be used in conjunction with daily traction stretches to optimize passive ROM.

Fig. 42-6 The Bayne and Klug²⁹ classification of radial ray deficiency. The thumb may be hypoplastic in each type. Type I patients have a slightly short radius without significant angulation of the wrist and no bowing of the ulna. Type II patients have a hypoplastic radius, the ulna may be slightly bowed, and the hand is radially deviated at the wrist. In type III (the most common presentation), the wrist is tethered to the remnant of the radius by a fibrous anlage, resulting in progressive radial deviation of the wrist with growth. In type IV, the radius is absent, the ulna is bowed (although often less so than in type III), the hand is radially deviated at the wrist, and the elbow may be unstable.

Table 42-1 Bayne and Klug's Classification of Radial Ray Deficiency

Type	Characteristics
I Short distal radius	Decreased growth of the distal radial epiphysis causes a short radius.
II Hypoplastic radius	The proximal and distal epiphysis of the radius are hypoplastic.
III Partial absence of the radius	The defect can be in the proximal, middle, or distal third of the radius. The hand is radially displaced. The ulna is thickened, shortened, and bowed radially. The wrist is unsupported.
IV Total absence	The hand is unsupported and severely radially displaced.

Bilateral cases of radial ray deficiency make up 50%^{5,28a} or more²⁹ of all cases. Even patients considered to have unilateral deficiency on the basis of radial hypoplasia alone have some hypoplasia in the opposite extremity (for example, a hypoplastic thumb).²⁹ Furthermore, a higher incidence in the right limb has been reported in unilateral cases.^{28a,31} Some studies of radial ray deficiency have indicated a greater incidence in males than in females.^{29,31}

Epidemiology

Birch-Jensen¹⁰ reported an incidence of 1 in 30,000 births, and Platt³² reported 1 in 100,000 births. More recently, Ekblom et al⁵ and McGuirk et al¹⁴ reported an incidence of 0.13 and 0.14 in 1000 live births, respectively. Most cases have no positive family history.^{3,33} However, a few familial cases have been published.³³ Temtamy and McKusick¹⁵ indicated that most inherited cases are transmitted in an autosomal dominant pattern with marked variability in expression. Autosomal regressive inheritance has been suggested. The possibility of teratogenic¹⁵ and environmental³² influence in sporadic cases has not been ruled out. The general consensus is that no clear etiology, genetic, or environmental factors have been found.¹¹

The diversity of associated anomalies with radial ray deficiency have been well documented.^{8,15,33-35} Tsuyuguchi et al³⁵ found an associated anomaly in 46% of 26 patients with radial ray deficiency. More recently, Ekblom et al⁵ noted an associated anomaly in 60.6% of 33 children with radial ray deficiency. In addition, associated anomalies are often associated with bilateral cases. Upton¹¹ reported associated anomalies were present in 40% of unilateral cases and in 77% of bilateral cases. Temtamy and McKusick¹⁵ classified associated anomalies into 10 subcategories (Box 42-1). The most commonly reported associated syndromes are Fanconi pancytopenia syndrome, thrombocytopenia-absent radius syndrome, Holt-Oram syndrome, associations with craniofacial syndromes, and VACTERL (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities).³⁴

Anatomy

The pattern of deficiency in the radial structures ranges from mild to severe involvement of the preaxial structures of the upper limb¹¹ (Table 42-2). James et al³¹ evaluated the pattern of deficiency in 124 patients with radial ray deficiency. In this study, distal deficiency often occurred in isolation. However, proximal deficiency was always associated with distal deficiency. Expression of deficiency generally moves from distal to proximal structures along the preaxial side of the limb. An exception to this rule was children with thrombocytopenia-absent radius syndrome. These children may present with an absent radius and a relatively well-developed thumb.^{31,32}

Box 42-1 Ten Subcategories of Associated Conditions With Radial Ray Deficiency

1. Radial defects with oral facial malformations
2. Radial defects with blood dyscrasias
3. Craniosynostosis–radial dysplasia syndrome
4. Radial defects with congenital heart disease: Holt-Oram syndrome
5. Radial defects with Duane anomaly
6. VACTERL
7. Radial defects with imperforate anus
8. Keutel-Kindermann syndrome
9. Chromosomal aberrations associated with radial defects
10. Thalidomide syndrome

Table 42-2 Commonly Absent and Abnormal Anatomy in Radial Ray Deficiency

Structure	Commonly Absent	Abnormal
Bone	Radius Scaphoid Trapezium Thumb metacarpal and phalanges	Scapula Clavicle Humerus Ulna Carpal bones
Muscle	Pectoralis major (clavicle or costal parts may be absent) Biceps (long head) Brachioradialis Anconeus Supinator Pronator teres Pronator quadratus Palmaris longus ECRL/ECRB EI Intrinsic/extrinsic muscles of the thumb	Pectoralis major Coracobrachialis Deltoid Brachialis Biceps (short head) Brachioradialis Supinator Pronator teres Palmaris longus ECRL/ECRB FCU/FCR FDM FDS/FDP EI EDC Intrinsic/extrinsic muscles of the thumb
Nerve	Myocutaneous nerve Radial nerve (distal to elbow)	Myocutaneous nerve Radial nerve Median nerve (innervates the radial aspect of the hand)

This table is by no means exhaustive, and many variations are known to occur.^{28a,29,33,36}

ECRL/ECRB, Extensor carpi radialis longus/extensor carpi radialis brevis; *EDC*, extensor digitorum communis; *EI*, extensor indicis; *FCU/FCR*, flexor carpi ulnaris/flexor carpi radialis; *FDM*, flexor digiti minimi; *FDS/FDP*, flexor digitorum superficialis/flexor digitorum profundus.

Proximally, the shoulder girdle can be affected in severe cases of radial ray deficiency.^{28a} The scapula may be reduced in size, and the clavicle is shorter and slightly more curved than normal. The humerus may be shortened and hypoplastic. Skeletal changes in the shoulder girdle may correspond with abnormal insertions of the pectoral major, pectoral minor, and deltoid muscles.

The long head of the biceps is frequently absent or abnormal.^{28a} When the long head of the biceps is present in patients with radial ray deficiency, it usually inserts into the lacertus fibrosus.³⁶ The short head of the biceps is always present but is usually fused with another muscle, such as the coracobrachialis or the forearm muscles.³⁶ The brachialis is usually present but may be normal, rudimentary, or fused.^{6,28a} The brachioradialis is usually absent if the radius is totally absent or is rudimentary with an abnormal insertion.^{28a,36} The joint ROM in the elbow may be impaired. Elbow stiffness in infancy may improve with time.³³ However, the absence of active elbow flexion is an important consideration for surgical management.^{29,33} Stiffness in elbow extension, along with absent or minimal active elbow flexion, is a contraindication for centralization or radialization of the wrist in patients with radial ray deficiency. Such procedures are not indicated, because the hand can reach midline at the face and body more easily in a radial position for daily activities.³⁷ Centering the hand on the forearm would worsen function.

In the forearm, if the radius is not totally absent, the proximal fragment of the bone is preserved. It can vary in size and shape and may or not be fused with the ulna.³⁶ When the radius is absent, the forearm typically achieves 60% of optimal growth.⁹ This proportion will remain throughout the child's development.⁹ The ulna is never normal in severe cases of radial ray deficiency.¹¹ This becomes more evident with severity of deformity as neurovascular and skeletal deficiencies become more pronounced.¹¹ The ulna is usually shortened, thickened, and curved, with the concavity toward the radial side^{28a,36} (Fig. 42-7). Muscle deficiencies in the forearm vary proportionately to the skeletal deficits.⁹ Muscles originating from the medial epicondyle (that is, the pronator teres and flexor carpi radialis) are usually well differentiated. However, they may have abnormal insertions, causing them to act as radial deviators of the hand.⁹ Alternatively, muscles originating from the lateral epicondyle are often affected. The brachioradialis, the extensor carpi radialis longus, and the extensor carpi radialis brevis are usually absent or abnormal. The supinator is typically absent, except in some cases in which the proximal radius is present.^{28a,36} The pronator teres may be absent if the radius is totally absent, or it may be rudimentary or fused with the biceps-brachialis mass, palmaris longus, or flexor carpi radialis when the radius is present.^{28a,36} The pronator quadratus is usually totally absent.³⁶

The length of the forearm has functional and cosmetic consequences. Patients are required to tailor their sleeves on clothing to accommodate shortened arm length (Fig. 42-8). Lamb³³ reported that their ability to be independent in toileting depends on their limb length, and that this especially affects patients who have bilateral involvement. Goldfarb et al³⁸ studied 21 adult patients (25 wrists) with radial ray deficiency, Bayne classification III or IV, who underwent centralization as a child (age average 22 months). The results suggested that the functional ability of these patients were more greatly affected by hand function than by wrist angulation or limb length. They indicated that many patients were able to compensate by using exaggerated trunk flexion to increase limb length. Of those treated in this study, seven patients were affected bilaterally, and four of these seven had bilateral centralization. Centralization of the wrist and hand on the ulna naturally provides some augmentation of limb length.³⁹

Radial deviation of the wrist on the forearm varies from 30 to 90 degrees.²⁸ The amount of radial deficiency is related to the degree of radial deviation, hand instability, and soft tissue deficiency.^{9,32,36} Patients with total absence of the radius have the most severe deviation and least function.^{28a} The radial carpal bones are frequently absent.^{28a,36} The scaphoid and trapezium are most often affected and are usually absent or fused to other bones.^{28a,36} With skeletal maturity, intercarpal fusions become more apparent.³³ Carpal deficiencies appear to be directly related to

Fig. 42-7 This radiograph shows the right upper extremity of a child with radial longitudinal deficiency type IV. The radius is absent, and the residual ulna is shortened and bowed.

Fig. 42-8 **A**, The length of the sleeves of this winter jacket was custom tailored for this 10-year-old child with bilateral radial longitudinal deficiency type IV. An adaptive zipper ring was attached to the zipper pull to compensate for decreased strength and precision in fine grasp. **B**, The child demonstrates an adaptive pencil grasp. The pencil is held in an interdigital grasp with stabilization against the thumb.

the deficiency of the thumb.^{9,35} Isolated thumb hypoplasia is the distalmost expression of radial ray deficiency. The clinical presentation and management of isolated thumb hypoplasia is discussed in Chapter 43. Hand anomalies in radial ray deficiency are often confined to the thumb, index finger, and long finger.⁹ Patients with radial ray deficiency may also have a degree of hypoplasia or aplasia of the thenar muscles.^{9,35}

Classifications for isolated thumb hypoplasia, such as that presented by Blauth, can generally be used to describe the range of deficiencies in the thumb associated with radial ray deficiency (see Chapter 43). The first metacarpal and intrinsic muscles of the thumb are abnormal or absent, depending on the severity of thumb hypoplasia. Camptodactyly of the digits, especially the index and long fingers, often occurs with restriction in metacarpophalangeal joint flexion.⁹ The

pattern of digit deficiency progresses in severity toward the radial side of the hand. In more severe cases, multiple joints can be stiff, thereby resembling severe arthrogryposis.³³ The extrinsic finger flexors and extensors may be abnormal. The extensor indicis may be absent or abnormal.³⁶

Patients with radial ray deficiency often function surprisingly well, despite the radial deviation at the wrist and hand anomalies.³⁶ However, the extent of hand involvement has an impact on patients' functional ability.³⁸ These patients use an altered pattern of prehension that corresponds to their anatomic findings. Because structure and function of the radial digits are generally poorer than those of the ulnar digits, the radial deviation has some advantage. In this position, the ulnar border of the hand is optimally positioned for manipulation of objects.³³ Careful consideration of a child's pattern of prehension, specifically observing the preferred digits for function, is essential before making surgical recommendations. Centralization of the wrist of a child who prefers to use the ulnar digits may place the more functional digits at a less advantageous position for prehension.

Surgeons should recognize the difference between patients with thumb and hand anomalies associated with radial ray deficiency and those with isolated thumb hypoplasia. Manske et al⁴⁰ studied 23 patients who had pollicization surgery and compared usage of the hand between patients with isolated thumb hypoplasia and those with associated conditions. Eighteen patients had associated conditions, including radial ray deficiency, mirror hand, and five-fingered hand. The five patients with isolated thumb hypoplasia had an average of 95% usage of their hand with little difference between handling large and small objects. Patients with associated conditions used their hands an average of 79% of the time. These patients did not use their hand with the pollicized digit for a third of activities with small objects. Whether patients with associated anomalies will achieve an optimal functional outcome after reconstructive procedures needs to be considered.

Changes in the arterial system are also present. The brachial artery is usually normal but is sometimes divided into two branches high in the arm or not divided at all at the elbow.^{28a,36} The ulnar artery is usually normal in the forearm, but the radial artery is often small or absent.^{9,28a,36} The interosseous arteries are usually well developed and may accompany the median nerve through the forearm and supply the radial distribution in the forearm.^{9,28a,36}

Although rare, changes in the nerve supply may affect the limb as proximal as the root of the brachial plexus.³⁶ More frequently, the myocutaneous nerve is absent or abnormal and joined with or replaced by the median nerve.³⁶ The radial nerve terminates at the level of the lateral epicondyle.^{9,28a,36} If this occurs, the sensory distribution of the radial side of the hand is supplied by a larger superficial dorsal branch of the median nerve that emerges high in the forearm.^{9,28a} This nerve also communicates with the sensory branch of the ulnar nerve on the dorsal aspect of the hand.^{28a} Riordan^{28a} noted that the median nerve was the most superficial structure on the radial aspect on the forearm. The ulnar nerve was usually normal.^{9,28a,36}

Evaluation

Patients with radial ray deficiency should be evaluated shortly after birth. Documentation of associated conditions is important, especially in patients with thrombocytopenia-absent radius syndrome and those with cardiac anomalies.

The presence or absence of active elbow flexion in infants with Bayne and Klug type III or IV radial ray anomalies should be appreciated (see Table 42-1). This may be difficult to discern because of a child's developmental status and should be evaluated again at the child's next appointment. A musculoskeletal examination of the child's volar creases and flexion and extension digital creases provides information about the integrity of the joints. If creases are present, then the joint has been in use. Patients with Bayne and Klug type III or IV radial ray deficiency should be referred immediately to physical or occupational therapy for passive stretches, which are more easily accomplished if begun at an early age.

Functional evaluation of the upper limb can begin when a child is 4 to 6 months of age. As mentioned previously, the radial deviation of the wrist may place the more functional ulnar digits in a position for function. Centralization of such a hand may inhibit a child's function. When evaluating fine motor function, surgeons should consider the following four factors:

1. The presence of active elbow flexion. Absent or minimal active elbow flexion is a contraindication for centralization surgery.^{29,33,41,42}
2. A radial or an ulnar approach to an object during reach. If a child uses the ulnar side of the hand to manipulate objects, then centralization may not be of benefit. If the radial side of the hand is used, then the surgeon should determine whether the patient has an efficient gross and fine grasp. If a patient uses a pattern of opposition with the thumb and digits for fine and gross grasp, then centralization is recommended. If a patient uses an interdigital grasp between the index and long fingers, centralization followed by pollicization is a possibility. However, this recommendation is contraindicated for those with significant associated anomalies in the hand.^{29,41,42}
3. The child's development. If a child has a unilateral impairment, fine and gross grasp in the unaffected hand should be evaluated. Does the patient consistently demonstrate a superior pincer grasp with the unaffected hand? This information helps to determine whether a child's fine grasp has reached appropriate maturation. A key observation period for prehension is 9 to 12 months of age, when the infant develops a pincer grasp.⁴³
4. The child's suitability for postoperative rehabilitation. Will the child comply with the splinting and therapy regime? For an older child, has he or she adapted sufficiently to be independent in daily skills. Children older than 12 years of age have usually learned to adapt well, and surgery is rarely indicated.^{11,41}

Surgical correction often presents the conflict between the wish for cosmetic acceptance versus the risk of functional loss.¹¹ Several possible outcomes of centralization surgery may negatively influence function.³³ These include shortening the forearm from surgical trauma to the distal ulnar epiphyseal plate.^{33,39} After centralization of the wrist, function can be compromised from the inevitably associated stiffness.³³ Frankel et al⁴² did not recommend centralization for most patients with bilateral radial ray deficiency because of the possibility of functional loss. Although gains in function and appearance are reported in several studies, the authors indicated the difficulty in objectively measuring their outcomes.^{33,39,44} Comparing treated and untreated patients with radial ray deficiency is challenging.^{8,38} No standardized method exists for evaluating preoperative and postoperative function to validate surgical interventions in these patients.³⁸ Difficulties in measuring outcomes include rarity and heterogeneity of the condition, the presence of confounding associated anomalies, challenges in obtaining preoperative data because of the young age at which patients undergo surgical intervention, and finding untreated patients as controls.^{38,45} Furthermore, those who are untreated use adaptive techniques and aids (such as Velcro on clothing) and function well in their daily living skills.⁸ Most studies use additional components, such as ROM, sensation, strength, and prehension, as a means of measuring function, but only a few measure performance in daily activities.⁴⁶ Further research is needed to validate surgical outcomes in patients with radial ray deficiency.

Nonoperative Management

Splinting, serial casting, and passive stretches of the upper limb begin immediately after birth to maximize ROM.^{11,33} Thermoplastic static progressive splints are effective in providing a prolonged stretch to the hand and wrist on the forearm. If serial casts are used, they must extend above the elbow.¹¹ Splinting and casting should always be secondary to routine passive stretching exercise.¹¹ Passive stretching of the hand out of the flexed, pronated position with gentle axial traction and ulnar deviation is the priority.¹¹ Initially, parents may have difficulty applying traction to the limb,

but its importance should be emphasized, because it is a critical component of the stretch that positions the carpus over the head of the ulna. Stretches should be conducted daily at every diaper change (approximately eight times a day). Finger contractures and limitations in elbow flexion also require passive ROM stretches to optimize ROM.³³ We prefer to provide intensive passive stretching from birth. Splinting at night is introduced when children are approximately 3 months of age. At this age, the limb size facilitates a more optimal and effective stretch in a splint. Splints are not worn during the day to allow fine motor and sensory development. Effective splinting and stretching of the limb can prevent the need for soft tissue release in patients with Bayne and Klug type III and IV radial dysplasia before centralization or radialization.¹¹

Operative Management

Indications for surgical management vary by type of radial ray deficiency. For mild type I cases, operative treatment is rarely required. In some type I patients and mild type II patients, Ilizarov distraction has been demonstrated to successfully lengthen the radius. In severe type II, III, and IV patients, centralization is often indicated provided that active elbow flexion is present. Centralization has numerous contraindications. It should not be offered to adults who have adjusted to the deformity, because it may worsen function. Deficient or absent active elbow flexion is usually considered a contraindication to centralization. Tethering of neurovascular structures (for example, a radially displaced median nerve) may preclude centralization. Associated systemic disorders limiting lifespan are considered contraindications.

In appropriately selected patients, centralization produces a more normal-appearing, better-functioning limb. The components of centralization include a wide release of radially based contracted soft tissues and excision of any remaining fibrous anlage, transposition and temporary pin fixation of the hand onto the ulna, possible transfer of the extensor carpi radialis and flexor carpi radialis muscles to the ulnar side of the wrist, and local fasciocutaneous flap closure of the resulting radial-sided skin deficit (Fig. 42-9).

Preoperative management seeks to improve outcomes. Stretching, splinting, and serial casting reduce the likelihood that tight soft tissues will produce relapse postoperatively. In addition, if the soft tissues are adequately compliant, less bone needs to be resected from the carpus to accommodate the distal ulna, and in some cases, no bone needs to be resected from the carpus.

Some authors advocate using an Ilizarov distractor for soft tissue distraction before centralization. In principle, this can be considered a more invasive form of aggressive precentralization splinting. Nanchahal and Tonkin⁴⁷ recommended using distraction to straighten the ulna and improve the position of the hand before centralization. They thought that the procedure preserved carpal bones that would otherwise need to be resected in more difficult centralizations. They examined the child at 3 months of age, and if the hand could not be reduced onto the distal ulna, then they recommended soft tissue distraction. They combined an open soft tissue release with distractor application, if needed. After a latency period of 1 week, they distracted at 1 mm per day, usually for 3 to 4 weeks. Recently, however, Manske et al⁴⁸ compared the long-term outcomes of patients treated with centralization alone versus external distraction followed by centralization. They found that soft tissue distraction using an external fixator did not prevent recurrence of the deformity and was associated with worse radial deviation and volar subluxation of the wrist on radiographs.⁴⁸

Several different incisions and approaches have been reported for centralization and its variations. Evans et al⁴⁹ recommended using a dorsoulnar-based bilobed flap with a transverse radial incision. Manske et al⁵⁰ described a transverse ulnar approach. Buck-Gramcko⁵¹ reported an S-shaped incision from the dorsum of the hand to the proximal third of the forearm. A lazy-S incision was also used by Nanchahal and Tonkin⁴⁷, who excised excess skin and subcutaneous tissue

Fig. 42-9 In carefully selected patients, centralization can produce a more normal-appearing hand with improved function. **A**, Partial absence of the radius with a bowed ulna (Bayne and Klug type III radial ray deficiency). The radial-sided myotendinous units, including the brachioradialis, the extensor carpi radialis longus, and the extensor carpi radialis brevis, are hypoplastic. A tethering radial fibrous anlage is present. The radiocarpal joint capsule is tight. The median nerve is displaced radially and is located in an abnormally superficial plane. A radial-sided skin deficit and an ulnar skin excess may be present. **B**, The new anatomy after centralization. Exposure is carried out through an incision overlying the wrist that can be lengthened with a Z-plasty if needed. Alternatively, a bilobed flap can be raised for exposure and subsequent radial-sided skin coverage. The median nerve is dissected and preserved. The radiocarpal joint capsule is released. When possible, carpal bones are preserved. Sometimes it is necessary to remove a slot of bone and cartilage from the carpus to accommodate the distal ulna. The extensor carpi ulnaris is shortened and sutured to itself to generate a counterbalancing ulnar force across the wrist. An osteotomy of the radius is stabilized with a pin emerging through the dorsal wrist. Excess skin may need to be excised from the ulnar side of the wrist after centralization. (BR, Brachioradialis; ECRB, extensor carpi radialis brevis; ECRL, extensor carpi radialis longus; ECU, extensor carpi ulnaris; FCU, flexor carpi ulnaris.)

from the ulnar side of the wrist as necessary. Regardless of the approach used, full access to the ulna and the radial extensor and flexor tendons is needed. The decision to use a local flap, such as a bilobed flap, is based on whether a skin deficit exists when the hand is repositioned. If soft tissue distraction has been used, then a dorsally based flap may not be necessary, and a Z-plasty or lazy-S incision may be adequate.

After an incision is made, soft tissue is released. The median nerve (replacing the radial nerve) lies very superficial and radial to its normal location and can be easily damaged. The median artery may accompany it. It is usually not necessary to identify the ulnar artery, but it may be the sole arterial supply to hand. The extensor retinaculum is divided (except on the ulnar side), and the radial-sided wrist extensors and flexors are divided. In type III patients, the fibrous anlage should be excised. The ulnocarpal joint capsule is raised as a distally based flap, and the ulnar head is freed, with an effort to preserve the epiphyseal vascularity. The carpus is then placed onto the ulna. Lamb³³ and Manske et al⁵⁰ favored resection of the central carpal bones to accommodate the ulna, whereas Bayne and Klug²⁹ and Buck-Gramcko⁵¹ retained the carpal bones to maximize length. Buck-Gramcko⁵¹ placed the ulna in a more radial position (radialization) to shorten the level arm available to the radial-sided deforming forces that may produce relapse. He also trans-

ferred the extensor carpi radialis and the flexor carpi radialis to the ulnar side of the wrist for the same reason.⁵¹ Most authors shave a portion of the distal ulna to facilitate placement into the carpus, while preventing damage to the growth plate. An ulnar osteotomy is performed if indicated (for bowing or to decrease length to accommodate retaining carpal bones). A Steinmann pin or K-wire is placed from the index metacarpal into the ulna.

When possible, the radial wrist extensor and flexor mass is transposed to the ulnar wrist. This may not be possible if the myotendinous units are very short, fibrotic, or not present. Bayne and Klug²⁹ recommended transfer of the extensor carpi ulnaris and flexor carpi ulnaris distally to the base of the small finger metacarpal to act as a dynamic sling in an effort to minimize relapse. After the skin is closed, a plaster long-arm cast is applied. The pin is removed usually 6 weeks postoperatively or later. Pollicization is considered 6 months later.

Damore et al⁴⁵ presented five main surgical and nonsurgical factors for recurrence of deformity after centralization surgery:

1. The inability to obtain complete correction at surgery
2. Inadequate radial soft tissue release
3. Premature fixation removal
4. Poor splint use
5. The natural tendency for there to be radial deviation for functional use of the ulnar border of the hand

Postoperative splinting is essential for the success of centralization and radialization procedures.^{11,29,33,45} A thermoplastic, forearm-based wrist splint with the fingers and thumb free is fabricated after the fixation is removed. Damore et al⁴⁵ recommended gradual weaning of the splint to night use only and continued use until skeletal maturity. Bayne and Klug²⁹ recommended a more restrictive regime whereby the child is splinted during the day until 6 years of age and then weaned to night splinting. Lamb³³ recommended postoperative splinting for at least 6 months. We prefer a splinting protocol of a minimum of 6 months postoperatively and then night splinting until skeletal maturity (Fig. 42-10). When patients are transitioning to use a night splint, they should be gradually introduced to activities with greater resistance and force. Ongoing active rehabilitation is not required after this acute phase of recovery. However, therapists should continue to provide ongoing functional evaluations to optimize daily functioning.

Recurrent deformity is often reported after centralization procedures for radial longitudinal deficiency.^{48,52} Ulnocarpal arthrodesis has been proposed as a successful salvage procedure in children who developed recurrent radial deviation after centralization.⁵³ Other experienced surgeons have moved away from centralization procedures because of the associated loss of wrist motion,

Fig. 42-10 This 5-year-old child had a type III radial longitudinal deficiency and a Blauth type IIIb hypoplastic thumb on the left side and is shown after centralization and pollicization for thumb reconstruction (see Chapter 43).

the negative impact on ulnar growth, and the high recurrence rate of radial deviation.⁵⁴ These authors favored soft tissue-only procedures (for example, tendon transfers, release of tight structures, and local skin flaps) combined with long-term splinting of the wrist at night. Alternative proposed solutions to reduce recurrence of the radial deformity after centralization in patients with types III or IV radial longitudinal deficiency include vascularized second metatarsophalangeal joint transfer to the distal ulna.⁵⁵ Although this procedure is performed to improve carpal stability and the potential for physal growth, the technique is technically demanding and was associated with a high rate of complications.

In addition to centralization procedures, some authors have attempted to lengthen the ulna in patients with radial longitudinal deficiency to increase forearm length. Farr et al⁵⁶ reported an average increase in ulnar length of 75% in six patients after distraction lengthening, but corrections in ulnar bowing and radial deviation were not maintained at a mean follow-up of 4 years. Other authors are less enthusiastic about ulnar lengthening in radial longitudinal deficiency.^{57,58}

Central Deficiency: Cleft Hand and Symbrachydactyly

Barsky⁵⁹ subclassified central anomalies as typical cleft hand and atypical cleft hand. To clarify the classification of hand anomalies, the decision to discard the term *atypical cleft hand* was made at the Fifth Congress of the International Federation of Societies of Surgery of the Hand in Paris in 1992.⁶⁰ In the following discussion, the current terminology will be used: cleft hand (to include the former typical cleft hand) and symbrachydactyly (to include the former atypical cleft hand).

CLEFT HAND

In patients with a cleft hand, the cleft is usually along the middle finger ray, but clefting between the ring and little fingers with hypoplasia of the little finger may be seen.⁶¹ In a review of 11 patients with clefts between the ring and little fingers, the cleft reached only into the distal palm in most hands, but in two hands, the cleft extended to the proximal palm.⁶² In all patients the little finger was hypoplastic, and interphalangeal joint motion was limited. In severe cases of cleft hand, the suppression of digits is greatest on the radial side of the hand, whereas in symbrachydactyly, the ulnar side of the hand is most affected. According to Lister,⁶⁰ a hand with no wrist deformity and only a thumb shows symbrachydactyly, and a hand with only a little finger shows cleft hand.

Confusion in classification can easily arise, because clefting has been classified as a failure of formation, whereas the associated polydactylies are defined as a duplication of parts. This ought to make them independent entities. Manske⁶³ reported on identical twins with elements of both clefting and central polysyndactyly in the same hand or in different hands of the same individual. He suggested a possible continuum from central polysyndactyly with osseous fusion through the cleft hand with hypertrophic bony structures to cleft hand with an absent middle finger ray and no other bony changes.⁶³ Ogino⁶⁴ thought that cleft hand was pathogenetically related to syndactyly and central polydactyly and represented failure of the induction of finger rays. All of the variations seen will never be reconciled into a single category. We think that classifying cleft hand under failure of formation (longitudinal, central) is a simple, though neither elegant nor rigorous, solution.

Several classification systems have been developed to reconcile the wide variation seen in typical cleft hand patients.⁶⁴⁻⁶⁶ We prefer Blauth and Falliner's classification,⁶⁶ because it is easy to remember and suggests the degree of complexity that may be required in the reconstruction.

Table 42-3 Blauth and Falliner's Classification of Cleft Hand

Type 1	Cleft hand with osseous aplasia
Type 2	Cleft hand with synostosis
Type 3	Cleft hand with aplasia and synostosis

They analyzed both the literature and their own 35 patients. They emphasized the value of radiographs in assessing morphology and stated that, in 40% of their cases, they thought the cleft was caused by synostosis. Their classification system is presented in Table 42-3.

The right side is more commonly involved than the left, and most patients are male.^{5,66} Cleft hand may be familial¹⁰ (Fig. 42-11). The mode of hereditary transmission varies widely, but overall, the risk of inheritance of cleft hand was about 20% according to Birch-Jensen.¹⁰ Although most cases of cleft hand are sporadic, when hereditary, it is often dominant.¹⁰

Epidemiology

Birch-Jensen¹⁰ studied the incidence of cleft hand in the general population. In his report, the term *split hand* corresponded to typical cleft hand, and *symbrachydactyly* carried its current meaning. The cases of atypical split hand appear to belong to both current classes and cannot be reassigned retrospectively. For this reason, the birth data presented slightly underestimated the true incidence of these conditions. The stated frequency at birth for cleft hand was 1 in 90,000, and the prevalence in the population was 1 in 112,000. McGuirk et al¹⁴ reported the incidence of longitudinal arrest, central, as 0.06 in 1000 of all congenital upper limb malformations. More recently Ekblom et al⁵ reported that central longitudinal deficiencies occurred with a frequency of 0.9 per 10,000 live births. Cleft hand and symbrachydactyly accounted for 1.4% and 2.6%, respectively, of all congenital upper limb anomalies.⁵ Ogino et al³ reported that cleft hand was seen in 2.6% of children with hand anomalies and symbrachydactyly in 5.1% of cases if atypical cleft hand and brachysyndactyly were interpreted as symbrachydactyly.

The deformities can be broadly classified as longitudinal failures of formation of the central ray of the hand.¹ These lesions may result from defects in the undifferentiated mesenchyme occurring early in life in embryos at stages XX to XXII, as suggested by Senrui et al.⁶⁷ This is supported by the finding that the vascular anomalies found in congenital hand lesions either by dissection⁶⁸ or at angiography⁶¹ correspond to an arrest in the development of the vascular tree at an appropriate early stage.⁶⁸ Surface markings can also suggest possible mechanisms involved in these deficiencies. For example, whorls are not normally seen in the interdigital areas of the distal palm in normal hands. Whorls are seen in cleft hands on the ulnar side of the cleft over the top of the rudimentary middle ray,⁶⁹ suggesting an association with, and confirming the suppression of, the central ray.

When other associated anomalies are present, inheritance patterns are usually autosomal dominant, as seen in cleft hand with major defects of the ulna, radius, clavicle, acetabulum, femur, tibia, or fibula; absent permanent teeth; nasolacrimal duct obstruction; eye defects; and onychia.⁷⁰ The ectrodactyly (congenital partial or complete absence of one or more digits), ectodermal dysplasia, and cleft lip and palate (EEC) syndrome is inherited in an autosomal dominant fashion, but about half of the cases are sporadic,⁷⁰ and great variability of expression is seen.⁷¹

Fig. 42-11 **A**, Although only one hand is involved, this patient has many features of typical cleft hand. A deep cleft is present in the center of the hand, and adjacent digits are relatively preserved. **B**, The volar view shows that the central cleft is actually wider than the first web space. The ring and little fingers are fused. **C**, A radiograph of the hand shows an unsatisfied third metacarpal, fused proximal phalanges of the fourth and fifth digits, a small distal nubbin for the little finger, and a tight first web space. **D**, Bilateral foot anomalies are seen with suppression of the central ray, soft tissue clefting, and well-proportioned but syndactylyzed border digits. **E**, Radiography of the right foot shows fusion of the third and fourth metacarpals, absence of the third toe, and a soft tissue cleft. The first surgical step in hand reconstruction in this patient was to ensure that grasp between the thumb and index was sufficient. When the patient was 5 years of age, a four-flap Z-plasty of the first web space was undertaken, along with reconstruction of the ulnar collateral ligament of the metacarpophalangeal joint of the thumb with fascia lata. **F**, After ensuring in therapy that the patient could transfer gross grasp to the reconstructed first web space, the redundant tissue of the cleft was excised, Z-plasties were performed along the incision lines, and the central cleft was closed in a simple fashion when the patient was 5½ years of age. **G**, A long segment of fascia lata was harvested and used to reconstruct the deep transverse metacarpal ligament. The fascia was passed in a figure-of-eight fashion around the necks of the metacarpals of the index and ring fingers and secured with a nonabsorbable suture. **H**, The patient has good hand function after cleft closure, because the function of the first web space was assessed, reconstructed, and rehabilitated before cleft closure was undertaken.

Lower extremity deformities (see Fig. 42-11), such as clefting, syndactyly, polydactyly, and tibial defects, occur with cleft hand.^{64,66} Patients with foot anomalies may have a deep, V-shaped cleft of the central hand, often with syndactyly of the remaining components, and do not have intercalary defects.⁵⁹ Syndromic associations in cleft hand are not common but must be considered because of their implications for overall treatment. Rüdiger et al⁷² first described the association of ectrodactyly, ectodermal dysplasia, and cleft lip and palate. Patients with the EEC syndrome can have significant problems during or after anesthesia, including difficulties with malnutrition, difficulty controlling body temperature (related to hypohidrosis), and persistent urinary tract infections.⁷³ Even more rare is the association of ectodermal dysplasia, ectrodactyly, and macular dystrophy (EEM syndrome) reported in an isolated community in Japan.⁷⁴ Cleft hand has occurred in patients with Silver-Russell syndrome, a form of dwarfism of prenatal onset.⁷⁵

Anatomy

Carpal anomalies are not seen in patients with a distal or partial cleft of the metacarpals.⁷⁶ Patients with complete defects of the metacarpals have defects confined to the distal carpal row. These include hypoplasia of the trapezoid, enlargement of the hamate, and splitting of the capitate. Fusion of the second metacarpal to the trapezoid, fusion of the capitate to the hamate, and fusion of the first metacarpal to the trapezium occurs.⁷⁶

Cleft hand may be seen on one side, with syndactyly or central polydactyly on the opposite side.⁶⁴ Associated anomalies usually include syndactyly of the thumb and index finger (Fig. 42-12) and syndactyly of the ring and little fingers. Cleft hand can be pathogenetically related to syndactyly and central polydactyly with failure of induction of finger rays, and triphalangeal thumb, shortened middle phalanx of the little finger, transverse phalanges, double metacarpals supporting a single digit (see Fig. 42-11), and combined metacarpals have been reported.⁶⁴

Nonoperative Management

Treatment for cleft hand varies widely depending on the presentation. Many patients present with little or no functional impairment, and operative treatment may be indicated only for cosmesis rather than functional gain.^{59,77} The inability to improve function in some cases was recognized even in the nineteenth century.⁷⁸ Evaluating function in patients with cleft hands before surgical treatment is critical, because prehension may be good and cosmesis the only issue (Fig. 42-13). Gross grasp within the cleft may be much more efficient than grasp between the thumb and index finger, and function may be compromised if the cleft is closed. Therefore a thorough evaluation of prehension and bimanual function is required before reconstruction is considered. For example, Ogino⁶⁴ recommended ablation of the interdigital cleft in patients with no missing finger or one missing finger. He did not recommend cleft closure in patients missing the index finger or the index and middle fingers and in patients missing three digits, because the ability to grasp large objects will be diminished.

Fig. 42-12 **A**, This 1-year-old patient had a cleft hand with absence of the middle finger and thumb-index syndactyly. **B**, A gross grasp was present in the central cleft. The tight, incomplete simple syndactyly between the thumb and index finger produced significant radial clinodactyly of the index finger. **C**, A preoperative radiograph showed very tight skeletal alignment of the first and second rays. The middle finger metacarpal was unsatisfied, and a wide, central soft tissue cleft was present. **D**, This oblique postoperative radiograph shows that the newly created first web space is wide, and that the second metacarpal is now unsatisfied, because the index finger was moved onto the stump of the middle metacarpal. **E**, The patient is able to grasp small and larger objects. Further correction of the radial clinodactyly of the index finger may be required when the patient is older.

Fig. 42-13 **A** and **B**, A two-fingered cleft hand with a sufficient web between the digits may prove very functional and not warrant reconstruction. **C**, A radiograph shows the two digits positioned in an excellent orientation for grasp. **D**, Hand function could not be improved with surgery.

Operative Management

Upton and Taghnia⁷⁷ summarized the key indications for operative intervention for cleft hand. These included severe flexion contracture of one or more digits, a malpositioned index ray that interferes with function, a tight syndactyly involving the thumb, and major functional limitations of the hand. Furthermore, they described the following reconstructive goals:

1. Preservation or reconstruction of a mobile, unscarred, and stable thumb
2. Transposition of the index ray to the ulnar side of the cleft
3. Creation of a wide, well-contoured first web space
4. Correction of index malrotation or deviation
5. Preservation of an intact (if present) adductor pollicis muscle
6. Creation of a satisfactory appearance

Timing of Operative Management

A tight thumb to index syndactyly should be released as soon as possible.⁶⁴ However, the child must be old enough to demonstrate the functional patterns that will be used in prehension. Generally, the following procedures involving flap transposition are best performed when patients are about 2 years of age, when the hand is larger than in early infancy, and the child has sufficiently sophisticated function to make use of the reconstruction. Ligamentous reconstruction is easier at this age. Rotation osteotomies can be readily performed in patients 5 to 6 years of age, when the skeleton is more mature.

Surgical Technique

Closure of the soft tissue cleft should achieve a smooth surface on the palm and dorsum of the hand and should produce a new central web that is natural in contour and correctly positioned. Barsky⁵⁹ described a hexagonal flap, based distally on one side of the cleft, to reconstruct the interdigital web (Fig. 42-14). He closed the cleft proximally with interdigitating, zigzag incisions. Kelikian and Doumanian⁷⁹ described treating cleft hand patients with a rectangular flap with its pedicle based at a level of the normal commissure, if one exists on the opposite hand. Ogino⁶⁴ preferred a small triangular flap, usually based on the ulnar side of the cleft, which could be used to break up the scar along the commissure. Finally, in patients with a generous amount of avail-

Fig. 42-14 Barsky⁵⁹ introduced a distally based hexagonal flap for reconstruction of the commissure in cleft hands. Proximal zigzag incisions are used in the closure.

able soft tissue, direct closure of the web may be possible using Z-plasties along the length of the volar and dorsal incisions to reduce the risk of scar contracture (see Fig. 42-11).

Various techniques have been used to reconstruct the deep transverse metacarpal ligament, one of the key steps to successful cleft hand reconstruction. Barsky⁵⁹ used drill holes and heavy gut sutures to oppose the metacarpal heads and removed unsatisfied metacarpals in the cleft. Ogino⁶⁴ and Tsuge and Watari⁸⁰ used ligamentous flaps designed on the adjacent sides of the flexor sheaths. Usually the A1 pulley is divided longitudinally at its attachment opposite the cleft and transposed across the cleft to be sutured to a corresponding flap from the other side (Fig. 42-15). This allows a reconstruction at the appropriate anatomic site, without excessive tension. Fascia lata is available in most patients and provides a ready source for ligament reconstruction (see Fig. 42-11). It is wound around the necks of the metacarpals in a figure-of-eight fashion to provide stable fixation of the cleft. Finally, an infrequently available but efficient option for donor material for reconstruction of the deep transverse metacarpal ligament is the use of ligaments or tendons from a part that is being discarded, such as the Achilles tendon from an amputated hypoplastic leg (Fig. 42-16). An intertendinous connection can be made between the extensor tendons of the digits on either side of the cleft to prevent future separation.⁸⁰

Fig. 42-15 Flexor tendon sheath, usually the A1 pulley, can be used to reconstruct the deep transverse metacarpal ligament. The sheaths are incised on the side opposite the cleft and then are transposed and sutured to each other.

Fig. 42-16 This hypoplastic leg (failure of formation of the tibia) had been amputated through the knee to allow fitting of a prosthesis. The Achilles tendon (held above the forceps) was dissected from the specimen and used for reconstruction of the deep transverse metacarpal ligament in a cleft hand. The extreme hypoplasia of the tendon suited the size of the desired reconstruction.

Ray fusion or osseous syndactyly is frequently seen in patients with cleft hand. Tsuge and Watari⁸⁰ attempted to separate these if the shape of the phalanges could be preserved. Angiography helped to evaluate for a common arterial supply, but the primary difficulty was the shared tendons and joint capsule. An interesting finding from their work was that the extensor tendons tend to fuse more proximally than the flexors. The gains from these extensive procedures may, however, be modest.

Syndactyly of the thumb and index finger is often seen (see Fig. 42-12), and the treatment for the central cleft must be planned with this in mind. One of the most satisfying reconstructions for patients with a large central cleft and complete syndactyly between the thumb and index finger is the Snow-Littler procedure.⁸¹ The digital portion of the syndactyly between the thumb and index finger is divided as for a typical syndactyly, with zigzag incisions and full-thickness skin grafts. A flap based on the palm is taken from the central cleft space on a neurovascular bundle and is used to resurface the newly created first web space (Fig. 42-17). Lateral pressure is placed to oppose the rays adjacent to the cleft to evaluate the amount of skin that can be resected in the area of the cleft.⁶⁴ The dorsal veins are preserved with the flap. All fibrous bands are released between the thumb and index finger. The venous drainage of the index finger is preserved by a dorsal skin bridge. The index finger is transposed on its neurovascular bundles⁸² at the level of the metacarpal base to close the cleft. The base of the middle metacarpal can be used for fusion to the base of the index (see Fig. 42-12), sometimes in the form of a bony peg. If the middle metacarpal is

Fig. 42-17 A volar flap is used in the Snow-Littler procedure. The technique provides a sensate flap to reconstruct the first web space and readily preserves the venous drainage of the index finger.

tiny or absent, transposition may not be possible. In such a case, it may be necessary to undertake a wedge osteotomy of the index finger to bring it into alignment without transposition. Proper alignment of the metacarpals is critical.⁸¹ Transverse metacarpals or phalanges that impede closure of the second and fourth metacarpals should be resected and the extensor hood reconstructed as necessary.⁶⁴ When transverse metacarpals are significant contributors to a joint, a portion of the bone may need to be preserved to retain stability of the joint.⁸⁰ Patients can have very good function after this procedure, with good grasp of small and larger objects (see Fig. 42-12).

Miura and Komada⁸³ designed an operation with simpler incisions than those used in the Snow-Littler operation for reconstruction of the first web space in cleft hand patients (Fig. 42-18). Incisions are made along the edge of the cleft and around the dorsal base of the index finger. The skin originally proximal to the incision on the index is used to close the new first web space. Although this is less demanding than the Snow-Littler operation,⁸¹ it probably will not provide sufficient tissue for release of a very tight thumb.

Another option for treating clefts with partial syndactyly of the thumb and index finger is a dorsally based flap, as described by Ogino⁶⁴ (Fig. 42-19). The excess volar skin is outlined in a zigzag fashion, an ulnar triangular flap is used to reconstruct the central web, and the incision is carried dorsally between the fingers adjacent to the cleft. A volar incision to open the first web

Fig. 42-18 Miura's procedure provides a simple reconstruction in a cleft hand patient with an adducted thumb but provides only a limited amount of tissue for web reconstruction. It is not useful in patients with syndactyly of the first web space.

Fig. 42-19 Ogino used a dorsally based flap to reconstruct the tight first web space in cleft hands with partial syndactyly of the thumb and index finger. The venous drainage of the index finger must be carefully preserved in this operation.

space is extended dorsally to a V-shaped apex over the dorsum of the index finger and is carried distally along the ulnar border of the index finger to meet the volar excision in the cleft. The dorsal flap is transposed to the dorsal aspect of the first web space after all the appropriate structures are divided. Additional full-thickness skin grafts may be required.

In some patients with syndactyly between the ring and little fingers, this may be released at the same time as the cleft closure.⁶⁴ Any flexion deformity of the proximal interphalangeal joint of the ring finger may not need to be corrected if the cleft surgery is performed before the patient is 1 year of age. If correction of the flexion deformity is necessary, the superficialis tendon is released from its insertion and secured to the base of the proximal phalanx volar to the reconstructed transverse metacarpal ligament. If the fingers adjacent to the cleft are divergent, the two slips of the superficialis tendon can be split and directed to the bases of the proximal phalanges of the fingers on either side of the cleft to help actively reduce the deviation.⁶⁴

A rotational osteotomy of the border digits can be performed, often at a later stage, to bring them into better alignment for grasp. They should be aligned so that the tips of the digits pass each other in flexion to allow a stronger power grasp.⁶⁰

Patients with clefting between the ring and little fingers may require surgery for cosmesis but not for function.⁶² Flaps, as described by Barsky,⁵⁹ have been used to line the web. Generally, the little finger does not tend to drift away, and little is required to maintain the metacarpal alignment.⁶²

Few studies document the outcomes of operative intervention for patients with cleft hand. In 1984 Tada⁸⁴ published his results of surgical treatment of 31 hands with central ray deficiency and reported satisfactory function and aesthetic outcomes. In 2008 Goldfarb et al⁸⁵ evaluated outcomes of bony and/or soft tissue closure of clefts in 12 patients (16 hands) using a subjective appearance-related visual analog scale completed by the parent and surgeon, ROM measurements, and radiographic divergence angles of the index and ring fingers. The authors noted improvement in all assessed outcomes at a minimum 5-year follow-up.⁸⁵ In a later study by Aleem et al,⁸⁶ narrowing of the first web space and index finger metacarpophalangeal joint abnormalities were associated with worse functional outcomes after surgical reconstruction of the cleft hand, whereas the presence of a transverse-lying metacarpal within the cleft was not predictive of outcome.⁸⁶ Further studies using well-defined and validated outcome measures are needed to better define outcomes of treatment for cleft hand, to refine operative indications, and to identify areas for improvement in perioperative management.

Authors' Preferences

Careful planning is the key factor for a successful procedure, and a preoperative evaluation of the existing prehension patterns cannot be emphasized too strongly (see Fig. 42-11). The greatest pitfall in reconstructing cleft hands is to close the cleft when function cannot be transferred to the first web, thereby losing gross grasp.

We prefer the Snow-Littler procedure⁸¹ in clefts with thumb-index syndactyly, because the volarly based flap is extremely robust and remains sensate. Any of the flaps described previously are satisfactory for closure of the web itself; however, the reconstruction of the deep transverse metacarpal ligament must be tight and the skin closure loose. The simplest option for reconstruction of the deep transverse metacarpal ligament is a transposed A1 pulley.

SYMBRACHYDACTYLY

Symbrachydactyly (Fig. 42-20) shows more severe suppression of hand formation, with attenuation of the marginal rays and central fingers sometimes represented by nubbins (Fig. 42-21).

Fig. 42-20 **A**, This 18-month-old child had symbrachydactyly of the right hand. No digital motion was observed, but some independent activity of the border metacarpals was noted. No grasp was present. The surgical plan was to discard the third ray, which was extremely rudimentary, and open a cleft to the level of the proximal metacarpals. Zigzag incisions were employed both dorsally and volarly to reduce the risk of contracture along the cleft (see Fig. 42-23). The unsatisfied raw areas were covered with full-thickness skin grafts. **B**, Postoperatively, the child uses the hand for simple grasp and should be able to use it to assist the master hand in light tasks.

Fig. 42-21 **A**, This 12-year-old's right hand had symbrachydactyly with a poor thumb and only nubbins representing the rest of the fingers. The patient was only able to hold very small objects in this hand. A two-stage reconstruction was performed. The first stage involved the thumb, and the second involved the ulnar digit. **B**, The lax thumb was reconstructed using an intercalary bone graft of fibular hemicortex, shown in a radiograph, to stabilize the thumb. A passive prosthesis was fitted on the ulnar side of the hand with a methylmethacrylate model of the proposed toe transfer. This prosthesis provided an opportunity to test various potential positions for the new digit. **C**, An AP arteriogram of the hand revealed an intact deep volar arch and a persistent median artery. A large ulnar artery was seen and was the planned vessel for arterial reconstruction. **D**, The second toe was transferred to the ulnar hand and held in place with two K-wires. The cartilage was shaved from the opposed surfaces at the osteosynthesis site. **E**, A postoperative volar view shows a second toe-to-ulnar hand transfer in place. The maximum extension is shown. It allows gross grasp sufficient for moderately sized objects. **F**, Pulp-to-pulp pinch is achieved mostly with thumb and metacarpal movement, with little movement in the transferred toe.

Table 42-4 Blauth and Gekeler's Symbrachydactyly Classification

Type	Characteristics
Type 1	Short finger type with short or absent middle phalanges and incomplete syndactyly
Type 2	Cleft hand with absence of one or more central fingers
Type 3	Monodactyly with a hypoplastic thumb and missing the remaining digits except for nail-bearing remnants
Type 4	Peromelia with absence of all digits except for small humps bearing nail fragments

Characteristically, symbrachydactyly includes rudimentary nails with very hypoplastic digits, whereas cleft hands have no rudimentary digits.⁶⁰

Blauth and Gekeler⁸⁷ attempted to classify symbrachydactyly (Table 42-4). Their paper was based on 19 of their own patients and 179 from the literature.

Symbrachydactyly is usually unilateral¹⁰ and without foot involvement or family history.⁵⁹

Epidemiology

In Birch-Jensen's study¹⁰ the incidence at birth was 1 in 40,000, and the prevalence in the population was 1 in 47,000. These patients may have deformities of the lower extremities, particularly clubfoot. Most cases of symbrachydactyly were sporadic; in the few hereditary cases, it appeared to be recessive in nature.

Anatomy

Most patients with symbrachydactyly have generalized hypoplasia of the carpal bones.⁷⁶ In some patients it is associated with pectoral hypoplasia and is a common feature in Poland syndrome.⁶⁴

Associated Conditions: Poland Syndrome

The original description of Poland syndrome was that of George Elt, a 27-year-old convict whose cadaver was dissected by Alfred Poland⁸⁸ in 1840 at Guy's Hospital in London. In 1921 Pol⁸⁹ published the first extensive description of a series of 20 cases involving pectoral muscle defects and hand deformities. He also noted 13 cases with isolated symbrachydactyly. The typical hand deformity seen in Poland syndrome is symbrachydactyly with absent or short middle phalanges,⁹⁰ syndactyly, and a normal or small thumb (Fig. 42-22). This corresponded well with Poland's original description. Surgical findings in the hand may include a common trunk forming the superficial or deep flexors and adhesion of the flexors to the surrounding tissues.⁶⁷

Many additional findings have been associated with Poland syndrome, including hypoplasia of the breast and nipple-areola complex,^{91,92} rib involvement,^{93,94} Pierre Robin sequence,⁹⁵ Moebius syndrome,^{93,96} dextrocardia,^{94,96} and morning glory syndrome, which features an unusual appearance of the optic disc, with a coloboma, and usually blindness thought to result from disturbances in closure of the optic disc.⁹⁷ Other associations include undescended testis, clubfoot, and cleft palate.⁹³

Fig. 42-22 A, This newborn had Poland syndrome. The sternal head of the pectoralis major muscle was absent, and the hand had symbrachydactyly. B, On radiography, the characteristic feature was absence of the middle phalanx, as seen in the little finger, or hypoplastic middle phalanges, as seen in the index and middle fingers. C, A volar view of the hands of the same patient at 7 years of age. The second through fourth webs have been released, but the thumb-index web space is tight and will require release. D, The dorsal view demonstrates that the fingers are both short and hypoplastic.

Epidemiology of Poland Syndrome

McGillivray and Lowry⁹³ examined 44 patients. A family history was obtained in 28 of them. The sternal head of the pectoralis major was absent in all patients, and symbrachydactyly was present in most. All family histories were negative. The authors found that the overall incidence was 1 in 32,000 live births in British Columbia, Canada. The prevalence in the population in 1975 was 1 in 57,000. Castilla et al⁹⁸ reviewed 599,109 live births in South America from 1967 to 1977. The overall incidence of complete Poland anomaly in South America was 1 in 50,000. They agreed with the Canadian study in showing a higher incidence in males, consistent unilaterality, preferential right-sidedness, no familial cases, and a history of prenatal drug exposure in a third of patients studied.

An autosomal dominant form of inheritance has been suggested, but with few positive family histories, the data are inconclusive for a familial cause for Poland syndrome.^{70,91,92} Engber⁹⁹ thought that cleft hand (as opposed to symbrachydactyly) in association with pectoral aplasia was an entity separate from Poland syndrome. It was a sporadic anomaly and families can be counseled accordingly.

Evaluation

Examining the function of a patient's hand deficiency is essential. In particular, the patterns of manipulation of small and large objects and of bimanual hand function will indicate the patient's preferred method of grasp. It is critical to determine whether grasp in a central cleft is the most efficient available. This clinical information can be supplemented by a radiologic assessment of the part with attention paid to the presence of hidden polydactylies and skeletal impediments to useful function.

Nonoperative Management

In some patients, surgery cannot produce functional or aesthetic improvement. Children should be followed every other year. A watchful follow-up helps to ensure the child and family that a team is in place, has an interest in their condition, and will keep them informed of advances as new concepts arise.

Operative Management

A preoperative evaluation of symbrachydactyly patients is critical to successful surgical management. Surgeons should determine whether the existing digits on the hand are functional, particularly if adduction of the border metacarpals is strong and purposeful. Are the border digits useful as they are, or can they be rendered sufficiently strong with a bony or ligamentous reconstruction or even with a tendon transfer? All patients with symbrachydactyly should initially be considered as candidates for toe-to-hand transfer if only to eliminate the possibility. Some of the procedures described in the following sections use toe parts as donor tissue. These must be undertaken with caution to preserve the option of whole toe transfer in appropriate patients.

Timing of Operative Management

Simple soft tissue procedures such as opening a cleft to enhance grasp can be performed as soon as a child demonstrates purposeful grasp with the opposite hand, at about 6 months of age. Non-vascularized toe phalanx transfers should be carried out before patients are 15 months of age. Free vascularized toes can be transferred to hypoplastic hands in patients as young as 1 year of age in some centers. We think this is best performed when patients are about 4 years of age, when the vascular structures are more robust and children may be better able to cooperate in therapy.

Surgical Technique

Patients with symbrachydactyly, no functioning digits, and significant hypoplasia may benefit from the creation of a cleft in the hand (see Fig. 42-20). A central ray or rays that are extremely hypoplastic can be discarded and a cleft opened to allow lateral pinch between the remaining radial and ulnar rays. Zigzag incisions, as used in syndactyly releases, and full-thickness skin grafts are required (Fig. 42-23). This may provide a simple helper hand when adequate proximal tissues for the addition of one or more toe transfers will probably not be available.

Patients with active digits that are too short for good function may benefit from nonvascularized toe proximal phalanx transfer, first described for this purpose by Carroll and Green.¹⁰⁰ These patients attempt to use the available digits for grasp, but the digits are of inadequate length to be useful. Preoperative strength and ROM in the digits to be reconstructed must be good. Among the large series describing this procedure, Buck-Gramcko and Pereira¹⁰¹ provided a most detailed

Fig. 42-23 An approach analogous to that used in syndactyly surgery is used in opening a cleft in symbrachydactyly. Zigzag incisions are planned on the volar and dorsal surfaces and interdigitate after release of the cleft. Hypoplastic central digits may need to be sacrificed in opening up the cleft. Raw surfaces are covered with full-thickness skin grafts (see Fig. 42-20 for clinical results).

description of the technique and a history of the procedure. It can be used to lengthen partially aplastic digits containing no proximal phalanx and to provide a hemiarthroplasty by retaining the plantar plate and collateral ligaments on the transplanted toe phalanx. The dissection of the toe proximal phalanx is started distally by opening the proximal interphalangeal joint. Proximally, the plantar plate of the metatarsophalangeal joint is divided at its proximal border if it is to be used for joint reconstruction. The periosteum of the phalanx must not be damaged; it is removed intact with the toe phalanx and improves the probability of successful revascularization. After the toe is removed, the extensor and flexor tendons are sewn together with nonabsorbable sutures to reduce the final shortening of the toe and are sewn proximally to the collateral ligament remnants to reduce lateral drift. If the toe phalanx is secured with an arthrodesis, the articular surface of the base of the proximal phalanx of the toe is shaved off, and the epiphysis is preserved. If a joint is reconstructed, the plantar plate is left free and not sutured.¹⁰¹

In preparing the hand, Goldberg and Watson¹⁰² used a zigzag incision over the dorsum of the finger. The skin incision did not violate the tip of the dissected pouch, reducing the risk of extrusion. The deeper soft tissue overlying the end of the stump was incised in a volar-dorsal direction, and the tissue was spread to produce attachments for the collateral ligaments. A longitudinal K-wire was placed for fixation.

Buck-Gramcko and Pereira¹⁰¹ reviewed 46 patients with 69 transferred phalanges and a mean follow-up of 40 months. The amount of postoperative growth was limited, but growth was better if the toe phalanx was transplanted in patients younger than 18 months of age. In the joint reconstruction patients, no factors correlated with the amount of motion achieved, and ROM was limited. They thought that hand function was improved, although this was not documented. Lister¹⁰³ thought that the insertion of nonvascularized toe phalanges might provide useful length in a much simpler operation than toe-to-hand transfer, if performed before patients are 15 months of age. Goldberg and Watson¹⁰² have shown that the percentage of open epiphyses at follow-up was greater in infants than in older children. In some cases, further distraction lengthening of the transplanted phalanx can be undertaken.¹⁰¹

Garagnani et al¹⁰⁴ recently reviewed long-term donor-site morbidity after nonvascularized toe phalangeal transfer in 40 children treated for digital hypoplasia. They concluded that donor-site complications were common, including donor toe instability, hypoplasia of adjacent phalanges, visible deformity that worsened with growth, difficulties with footwear, and emotional problems

related foot appearance.¹⁰⁴ These results highlighted that donor morbidity should not be overlooked in the preoperative discussion for nonvascularized toe phalanx transfers.

Another option is segmental transposition to augment a digit. Dobyns¹⁰⁵ defined this as the transfer in the same hand of a significant segment of a digit with one or more neurovascular pedicles to another digit to augment its size or length. He considered this particularly useful in small hands with a short thumb and index. Transposing the index remnant onto the thumb and discarding the proximal index ray provided a longer thumb and a deeper first web space.

Authors' Preferences

In deciding on the surgical treatment of symbrachydactyly, our first consideration is the preoperative function of the existing hand. For hands that are extremely rudimentary with poorly formed metacarpals and little intrinsic muscle function, the creation of a cleft in the hand may allow light grasp. Stronger hands, particularly those with a functional or reconstructible thumb, will often benefit from toe-to-hand transfer. Only hands with good individual finger and thumb function and a rudimentary grasp will benefit from a nonvascularized toe phalanx transfer.

We think that the gains from whole toe transfer in most cases of symbrachydactyly outweigh the gains from nonvascularized toe phalanx transfer. The key factor is to determine whether the hand is sufficiently developed to allow reconstruction of the existing digits or to support toe transfer, or, if the hand is extremely hypoplastic, whether to open a cleft in the center to facilitate simple side-to-side pinch. Ablation of the nubbins should generally be left to the discretion of the child. In all of these patients, the family should be prepared to expect a helper hand rather than a hand with subtle dexterity.

Future Considerations

Despite the ongoing research into the underlying causes and manifestations of these congenital differences of the hand, future management will probably change either as a result of a better understanding of the genetics involved or as a result of technical advances. Genetic developments may lead to early diagnosis and potential elimination of these defects.¹⁰ We may look forward to a time when rejection reactions are sufficiently controlled to allow elective hand transplantation without the need for long-term immunotherapy.

New techniques untried by most hand surgeons may lead to new avenues of therapy. For example, Ipsen and Barfred¹⁰⁶ described an unusual and complex reconstruction for cleft hand. They reported the case of a 12-year-old patient with two digits: a broad, large radial digit and an unstable, small ulnar digit. The ulnar digit did not have a carpometacarpal joint and was not animated. A new basal joint for the ulnar digit was created using a Swanson arthroplasty, and the flexor carpi ulnaris, extensor carpi ulnaris, and extensor digitorum communis tendons were transferred to the ulnar digit for animation. An additional tendon transfer to the radial digit was later required to provide good adduction. Key pinch was achieved. The use of the Swanson arthroplasty in young children to reconstruct a previously nonexistent joint is not yet a standard technique and must be considered with caution, because the durability of these prostheses over many decades of hard use has not been demonstrated. Long-term follow-up will be required to fully evaluate this procedure.

Other technical advances may facilitate our treatment of these unusual and challenging anomalies. We must remember, however, that function is crucial, and that no operation, however fascinating and elegant technically, is worthwhile if the child does not make use of the reconstruction.

ULNAR RAY DEFICIENCY: POSTAXIAL ANOMALY

Ulnar ray deficiency is the absence or hypoplasia of the ulna. It is generally characterized by a degree of limitation in the elbow joint, a shortened forearm, an ulnarly deviated wrist, and two or three radial digits in the hand. However, its clinical presentation is more variable than radial ray deficiency.^{11,34,107} The deformities in the elbow, wrist, and hand are highly variable.¹⁰⁸ The degree of carpal or ulnar deficiency has no apparent relationship to the position of the hand on the forearm.⁹ Hand anomalies can vary, with deficits in the radial, central, and ulnar digits with no specific pattern.⁹

Several classifications have been developed for ulnar ray deficiency.¹⁰⁸⁻¹¹² The classification from Dobyns et al⁹ (known as *Bayne's classification*) combines several other works and incorporates both elbow and ulna characteristics. It is considered to be the most clinically useful (Table 42-5).¹¹

Cole and Manske¹¹⁰ evaluated 45 limbs with ulnar ray deficiency and observed that 73% had abnormalities in the thumb and first web space. Twenty-eight of the 53 surgical procedures recommended were targeted at improving function in these two anatomic structures. They developed the following classification according to the thumb and first web that may assist with surgical recommendations (Table 42-6).

Table 42-5 Bayne's Classification of Ulnar Ray Deficiency

Type	Characteristics
I Hypoplasia of the ulna	Presence of distal and proximal ulnar epiphysis
II Partial aplasia of the ulna	Presence of the distal or middle third of the ulna
III Total aplasia of the ulna	Complete absence of the ulna
IV Radiohumeral synostosis	Fusion of the radius to the humerus

Table 42-6 Cole and Manske's Classification of Thumb and First Web Space in Ulnar Ray Deficiency

Type	Characteristics
Type A	The thumb and first web are normal.
Type B	The first web has mild deficiency, mild thumb hypoplasia, intact extrinsic tendon function, and opposition function.
Type C	The thumb has varying degrees of hypoplasia, and the first web has moderate to severe deficiency, including thumb-index syndactyly, often associated with malrotation of the thumb into the plane of the other digits, loss of opposition, and dysfunction of the extrinsic tendons.
Type D	The thumb is absent.

Epidemiology

Absence or hypoplasia of the ulna is one of the rarest congenital malformations of the upper extremity.^{107,113} In a recent study, Ekblom et al⁵ documented the incidence of ulnar dysplasia as 1 in 10,000 live births, accounting for 4.3 % of all congenital limb anomalies. McGuirk et al¹⁴ reported a lower incidence of 0.08 in 1000 among patients with congenital upper extremity malformations. Most cases are sporadic^{8,15,34,112} with no patterns of family inheritance.^{3,15,114} However, inheritance of three consecutive generations was reported.¹¹⁵ A simple pattern of inheritance is indicated in a small subgroup of these patients.¹⁵ The role of genetic and environmental factors in the cause of ulnar ray deficiency is not well understood.^{9,15}

Ulnar ray deficiency occurs bilaterally in approximately one of every three cases.^{110,112,116} The incidence is slightly increased in males with a ratio of 3:2^{107,112} or greater.^{5,110} Generally, there is no difference in right to left incidence.^{5,107,108,110,112}

The three most common syndromes related to ulnar ray deficiency are Cornelia de Lange syndrome, femur-fibula-ulna syndrome (or proximal focal femoral deficiency [PFFD]), and Schinzel syndrome.¹⁵ The last two syndromes are very rare. Swanson et al¹¹² found associated anomalies in the lower extremity in 41.5% of patients. Other associated conditions include the following:

- Contralateral hand defects¹¹⁶
- Clubfoot or associated anomalies of the lower extremity^{108,109,112,114}
- Scoliosis^{108,112,116}
- Spina bifida¹¹⁴
- Congenital dislocation of the hip^{107,109,114}
- Congenital coxa vara^{108,112}
- Oral facial malformations^{15,112,116}

Anatomy

Anatomic manifestations of ulnar ray deficiency are highly variable^{112,116} (Table 42-7). The previously mentioned classification systems were developed to provide a framework for understanding the anatomy of the forearm and hand. No correlation has been noted between the severity of ulnar deficiency, elbow deformity, and the degree of ulnar deviation at the radiocarpal joint.¹¹⁶ The proximal structures can also be involved, including hypoplasia of the shoulder structures, shortened humerus, and failure of differentiation of the elbow joint.⁹

Unlike radial ray deficiency, ulnar deficiencies most frequently present as partial absences.⁹ The articulation of the remaining portion of the ulna to the humerus is generally reasonably good,¹¹³ but radial head dislocation^{113,116} or radioulnar synostosis^{9,116} may occur. The ulna may be ankylosed to the humerus.^{8,9} Flexion deformities at the elbow often occur when the ulna is absent.⁹ In older children, restriction in elbow range is usually the result of radial head dislocation.⁹

Patients can compensate for restricted elbow and forearm movement by using shoulder and wrist movement.^{107,109} If functional deficits persist, surgical management of the humerus or forearm may optimize positioning of the upper extremity for function.^{107,109} Elbow flexion contractures may also pose difficulties with dressing activities. A surgical release may enhance function.¹⁰⁷

Ulnar bowing of the radius occurs in the forearm.^{8,116} The ulna is short, and the absent distal ulna may be replaced by a fibrocartilaginous anlage.¹¹³ This band of tissue restricts longitudinal growth,¹¹⁷ thereby restricting wrist motion and possibly contributing to the bowing of the radius.⁸

Table 42-7 Commonly Absent or Abnormal Anatomy in Ulnar Ray Deficiency

Structure	Commonly Absent	Abnormal
Bone	Ulnar carpal bones Ulnar metacarpals and digits	Shoulder girdle Humerus Ulna Radius Carpal bones Digits Thumb Triceps
Muscle	Triceps EDC of D5 EDM Extensor carpi ulnaris Palmaris longus FDP of D5 FCU	
Nerve	Superficial radial nerve at the level of the lateral epicondyle	

This table is by no means exhaustive, and many variations are known to occur.^{8,11,110,114}

D5, Fifth digit; EDC, extensor digitorum communis; EDM, extensor digiti minimi; FCU, flexor carpi ulnaris; FDP, flexor digitorum profundus.

The wrist is generally slender because of the absence of the ulnar carpal bones.⁹ The remaining carpal bones articulate with the distal radius.¹¹³ Broudy and Smith¹¹⁶ observed that the carpal bones were always affected with a common pattern of absence of the carpal bones proximal to any missing digital rays.¹¹⁶ Radial deviation at the wrist was decreased in all patients. They also observed a delay in appearance of carpal ossification centers in 18 of 26 limbs studied.

Less than a third of patients have fixed ulnar deviation at the wrist, and most are able to bring their wrist and hands into neutral position.⁸ Ulnar deviation at the wrist is generally nonprogressive and does not cause significant functional difficulties.¹¹⁶ Significant ulnar deviation can be prevented by early surgical management, and late or persistent deformity can be managed with an osteotomy if functional difficulties arise.

Ectrodactyly is the most common deformity in the hand.¹¹⁶ The remaining digits may show some degree of syndactyly.^{112,116} A correlation between the type or degree of ulnar deficiency and the location or number of absent digits has not been found.¹¹⁶ However, ulnar digits are absent more often than radial digits.¹¹⁶

Mild to moderate hypoplasia typically occurs in the thumb.¹¹⁶ Cole and Manske¹¹⁰ found thumb and first web space deficiencies in 73 % of the cases studied (see Table 42-6).

The radial digits are often preserved in patients with ulnar ray deficiency.¹¹⁶ Function is good in patients with opposition between the thumb and the radial digits. They are able to manage dressing, toileting, eating, and writing activities.¹¹⁸ Otherwise, reconstructive procedures for the thumb and web spaces may enhance opposition and prehension.¹¹⁶ Patients without opposition

will have impaired prehension. Adaptive prehension, such as an interdigital grasp and techniques or aids, may be used to facilitate independence. Despite altered prehension, most patients do not have difficulties in their activities of daily living.¹¹⁸

Evaluation

Children with ulnar ray deficiency should be initially evaluated shortly after birth. Evaluating wrist deviation and finger anomalies, such as camptodactyly and syndactyly, is important at the initial visit. Patients with contractures are referred for occupational and/or physical therapy. Early detection of contractures in the wrist and fingers can be managed through stretching or splinting to maximize ROM.

Nonoperative Management

The rehabilitation of infants with ulnar ray deficiency is focused on maximizing ROM and preventing contractures in the available joints. Passive ROM stretches of ulnar deviation contractures at the wrist and camptodactyly of the fingers are initiated as early as possible. Patients can wear a thermoplastic forearm-based wrist, hand, and finger splint at night to stretch the wrist into neutral alignment. This splint can be beneficial for children with camptodactyly to provide a prolonged stretch of the proximal interphalangeal joint into extension. Periods of stretching and splinting may be required throughout childhood to maintain optimal function. Caregivers should be advised on how to monitor their child's ROM.

Caregivers are instructed to promote bimanual activity to encourage their child to optimize the use of the affected limb. Therapists may suggest specific toys and activities to promote bimanual skills. For children beginning school, therapists assist with the acquisition of specific daily living skills such as learning to zip up a coat. As patients mature and develop specific hobbies and interests, therapists may assist in making these activities feasible, for example, by providing prosthetic adaptations for sporting equipment and musical instruments (see Fig. 42-4).

Operative Management

Ulnar ray deficiency can present quite variably. Therefore indications for operative management should be considered relative and not absolute; an individualized treatment plan should be stressed. Clinical outcome studies have been very limited because of the rarity of the condition. Elements of ulnar ray deficiency that may limit function and are often amenable to correction or improvement include syndactyly, first web space contracture, thumb duplication, thumb hypoplasia or malposition, restriction of growth with bowing of the radius from a tethering ulnar fibrous anlage, elbow stiffness, and elbow instability.

Syndactyly may be simple or complex. Standard release techniques work well for these deformities in many patients. However, for those with severe ectrodactyly, regional or distant flaps may need to be introduced to further separate the digits to allow a pincer grasp. First web space

contractures can be released with a Z-plasty or with other local flaps. The thumb ray may be present but poorly positioned, with the thumb pad in the same plane as the other digits. In such cases, the thumb may be rotated into a more advantageous position, allowing pulp-to-pulp pinch.

Carroll and Bowers,¹⁰⁷ Ogden et al,¹⁰⁸ and Broudy and Smith¹¹⁶ recommended excision of the fibrous ulnar anlage to prevent growth restriction and exacerbation of radial bowing. In patients with an unstable elbow and chronic dislocation of the radial head, excision of the proximal radius may be combined with excision of the distal ulna to form a one-bone forearm. Although the child can no longer pronate or supinate postoperatively, the elbow usually is stable.

Miller et al¹⁰⁹ recommended rotational humeral osteotomy in patients whose involved hand is positioned on the flank or buttock at rest and who cannot effectively place the hand in a functional position in front of the body. The affected forearm is also frequently malrotated; however, forearm osteotomies are rarely needed to improve function.⁵⁴

LONGITUDINAL INTERSEGMENTAL DEFICIENCY

From 1958 to 1962, the incidence of children with longitudinal intersegmental deficiency related to the ingestion of the sedative thalidomide by expectant mothers increased.^{119,120} These children typically presented with absence or deficiency in the bones between the hand and shoulder. Their hands or rudimentary fingers arose directly from the distal end of the remaining shoulder¹²⁰ (Fig. 42-24).

This condition was initially defined as intercalary deficiency, because the middle portion of the limb was absent or deficient, but the proximal and distal portions were present.¹²¹ The existence of true intercalary deficiencies was later questioned.¹ Although the condition affects mainly the long bones in the limb, the distal portion is never truly normal.^{1,122} Therefore these conditions are classified as a variation of longitudinal failure of formation of parts.¹

Fig. 42-24 A radiograph of a newborn with longitudinal intersegmental deficiency.

Table 42-8 Frantz and O’Rahilly’s Classification of Longitudinal Intersegmental Deficiency

Type	Characteristics
1: Complete	Absence of the proximal portion of the upper limb Hand attached to the trunk
2: Proximal	Absence of the humerus Forearm bone between the hand and trunk
3: Distal	Distal absence of the radius and ulna Hand attached to the humerus

Table 42-9 Tytherleigh-Strong and Hooper’s Classification of Longitudinal Intersegmental Deficiency

Type	Characteristics
A	An abnormal humerus with an abnormal single forearm bone
B	An abnormal humerus with an abnormal radius and ulna
C	An abnormal humerus fused to a forearm bone or bones

Attempts to further classify the conditions are reported. Frantz and O’Rahilly¹²¹ developed a classification system that consisted of three subtypes (Table 42-8). More recently, Tytherleigh-Strong and Hooper¹²² demonstrated that not all patients with longitudinal intersegmental deficiency could be classified under this system. Their classification system is shown in Table 42-9.

Epidemiology

Longitudinal intersegmental deficiencies account for 0.8% of congenital upper limb malformations.³² McGuirk et al¹⁴ reported an incidence of 0.06 in 1000. This condition is generally sporadic¹²¹ and can be induced by the use of thalidomide during pregnancy.¹¹⁹ A variety of cardiac malformations are associated with longitudinal intersegmental deficiencies.¹²⁰ Other associated conditions include Robert syndrome, cleft lip and/or palate, Holt-Oram syndrome, and adactyly-adontia syndrome.¹⁵

The pathogenesis of longitudinal intersegmental deficiencies is not completely known.¹²³ Thalidomide decreases growth in the limb-bud mesenchyme.¹²⁴ Tabin¹²⁵ proposed a theory using the progress-zone model to explain the pattern of perseveration of distal structures. According to the theory, thalidomide exposure causes the apical ectodermal ridge to produce fibroblast growth factor, which leads to respecification of cells in the limb bud. Others disagree that the apical ectodermal ridge plays a role because of the timing of limb development and thalidomide exposure.^{123,126} Last, evidence of involvement of the sensory nervous system in the pathogenesis of the limb deficiency has been shown.¹²³

Anatomy

Longitudinal intersegmental deficiencies are usually bilateral.³² Tytherleigh-Strong and Hooper¹²² studied 44 patients. Twenty patients were affected bilaterally, and just more than half had symmetrical deficiencies. Frantz and O'Rahilly,¹²¹ however, found that bilateral skeletal deficiencies are usually not symmetrical. In a cohort of patients affected by thalidomide in West Germany, half of the sample had only upper limb deficiencies. The other patients had a variation of upper and lower limb, ear, and other malformations.¹²⁰ Other studies of patients affected by thalidomide demonstrated that upper limb deficiencies were characteristically on the radial side.^{123,127} Variations of deficiency in the hand have a varying number of digits.¹²¹

Patients who are affected bilaterally without lower extremity involvement, often learn to become adept in using their feet for function and dexterity.²¹ Typically, functional problems are toileting and feeding activities. Therapy involving the use of adaptive devices and training is required to facilitate independence in daily living. Those who are affected unilaterally can use their affected hand with or without prostheses to assist their dominant unaffected hand to perform bilateral activities.

Evaluation

Children with longitudinal intersegmental deficiency should be initially seen within the first 3 months after birth. Those with joint contractures that require passive ROM exercises or splinting are referred for rehabilitation. Therapy is initiated at this time to work with the child and family to promote developmental milestones and to facilitate use of the lower extremities for children with bilateral involvement.

Nonoperative Management

Joint contractures such as camptodactyly are managed with passive stretches to maximize joint range. Thermoplastic splints may be required in severe cases.

Patients with longitudinal intersegmental deficiencies may be candidates for prosthetic management (see Fig. 42-4).²¹ Control of a terminal device can be designed using finger access, depending on the length of a patient's limb. The challenge in designing prostheses for these patients is to produce a simple and lightweight device; otherwise, compliance with the device will be low.²¹

Operative Management

There are few indications for operative management in patients with longitudinal intersegmental deficiency. Overgrowth of the distal humerus may result in bone exposure, requiring bone debridement and soft tissue closure. Some procedures need to be repeated until humeral growth ceases.²¹

Function may be improved by releasing syndactylized digits and web space contractures. Tendon transfers may improve opposition in selected cases. In severe cases, stump lengthening, through bone grafting or distraction osteogenesis, has been performed to facilitate prosthetic fitting. In rare cases in which the hand is severely deficient but a forearm component is present, a Krukenberg procedure has been recommended to provide prehension.²¹

KEY POINTS

- Evaluating a child's functional capacity is the most important step in developing a treatment plan.
- Prosthetic management is only infrequently accepted by children with congenital differences of the upper extremities.
- Some patients lose function after centralization of the wrist.
- Centralization of the wrist will probably be unsuccessful if preoperative stretching and splinting does not achieve passive correction of the deformity.
- Prolonged splinting may be required to maintain a centralized position.
- Patients with cleft hand usually have good function that should not be impaired by efforts to improve cosmesis.
- Intermetacarpal movement is critical for success in toe-to-hand transfer in symbrachydactyly patients.
- The entire extremity, including the chest wall, should always be examined.

The Hypoplastic Thumb and Absent Thumb

Joseph Upton III • Christopher J. Coombs • Daniel J. Wilks

child with thumb hypoplasia may present many unique problems with both grasp and digital prehension. The anatomic abnormalities seen with small or absent thumbs span a continuum ranging from minimal muscle and size discrepancies to complete aplasia. A thumb should be considered hypoplastic when there is a deficiency of any one or all of the structures that contribute to the normal structure.

Deficiencies of the axial skeleton, joints, intrinsic or extrinsic myotendinous units, or the soft tissue envelope can occur as an isolated deformity, in unison, in conjunction with other problems in the hand, or as part of generalized syndromes. When considered as a single diagnostic entity, thumb hypoplasia is one of the most common congenital conditions treated by hand surgeons. In our registry of approximately 8200 hands treated at the Boston Children's Hospital, hypoplastic or absent first rays are listed as a primary or secondary diagnosis in 2488 of the hands.

The impact of a hypoplastic or an absent thumb on hand function is not only related to the degree of the deformity but also to the severity of additional problems in the ipsilateral extremity. Cognitive function and cortical representation of the thumb will also have a great bearing on the child's ability to use his or her thumb. However, patients with severe central neurologic deficits may not benefit from the most sophisticated and elegant reconstructions. Decisions made in the treatment of these children directly affect not only the child, but also the family, physicians, and other care providers, who should be consulted when appropriate.

EMBRYOLOGY

Since Saunders' classic experiments performed on chicken embryos over 60 years ago,¹ much has been discovered about the intricate interplay of genes, proteins, and transcription factors that consistently produce the recognizable and vastly complex human limb. Although many of the molecular mechanisms are yet to be fully elucidated, great advances in the understanding of limb development have recently occurred through the application of molecular biology, animal models, and clinical genetics.

Streeter² described vertebrate embryo development as occurring along a preprogrammed path of 23 steps (called *Carnegie stages*). By day 30 of embryogenesis (Carnegie stage 9), the upper limb bud (at this stage called *Wolff's crest*) appears as a swelling on the ventrolateral sides of the embryo. By day 56 (Carnegie stage 23), nutrient vessel penetration of the humerus and distal phalangeal ossification signifies the conclusion of embryogenesis. Formation of all structures within the upper limb is complete.

During the fetal period that follows, growth of the upper limb occurs differentially.

Development of the limb (Fig. 43-1) progresses along three axes: proximodistal, anteroposterior (or radioulnar), and dorsoventral (or dorsovolar).³ Differentiation and formation along each axis is coordinated by chemical cascades initiated by discrete signaling centers.⁴

Proximodistal growth is thought to be coordinated by the apical ectodermal ridge (AER). This is an area of thickened, specialized ectoderm that covers the underlying mesoderm, known as the *progress zone* (PZ). The AER caps the developing limb bud and primitive hand plate as it forms, until separation of the digits occurs. Saunders' experimental work showing that earlier removal of the AER produced more proximal limb truncation led to the progress zone hypothesis of proximodistal formation. The presence of an AER-secreted morphogen was suggested by

Wolpert,⁵ which through its action on the underlying PZ maintained the cells in an uncommitted state. As the limb enlarges, cells too proximal to be influenced by the diffusible morphogen then differentiate. Molecular studies have since confirmed Wolpert's assertion and identified fibroblast growth factor (FGF) to be the morphogen.⁶

However, selective genetic knockout of the *FGF* gene does not replicate the clinical effects of surgical ablation of the AER as observed by Saunders.¹ Rather, these embryos continue to develop distalmost features, yet have a reduction of proximal structures.^{7,8} This finding, taken with other studies, has led to a shift away from the progress zone hypothesis and development of new theories, such as the early specification (all components of the limb are present early and expand with growth) and the two-signal model (an additional signal, perhaps retinoic acid, is secreted proximally).⁹⁻¹¹

Digit number and digit-specific morphology is established by the anteroposterior axis, which is governed by a further area of specialized ectoderm, found in the axilla of the developing limb bud within the PZ; that is, the ZPA. Consistent with the mechanisms of *FGF*-derived proximodistal growth, anteroposterior patterning occurs as a result of a diffusion driven, activator/inhibitor instability model; in this situation governed by *Sonic Hedgehog* (*SHH*) expression from the ZPA.¹²

SHH manifests its action through *HOXA* and *HOXD* genes. Whereas *HOXA13* and *HOXD13* are found in all digits, *HOXD10* through *HOXD12* are expressed in the fingers only.¹³ *HOXD13* displays a relatively limited response to *SHH*.

SHH also acts to inhibit truncation of the *GLI3* transcription factor. An absence of *SHH*, as found within the anterior hand plate, is therefore associated with an abundance of the truncated form (*GLI3R*), which is a strong transcriptional repressor. A posterior to anterior *SHH* gradient is therefore generated along with a reciprocal anterior to posterior *GLI3R* gradient. Increased levels of *GLI3R* and reduced levels of *SHH* on the anterior aspect of the hand plate are thought to lead to thumb development through second messenger mechanisms.

Specific defects in genes regulating limb patterning are associated with recognized thumb anomalies. For example, mutation of *HOXA13* causes hand-foot-uterus syndrome, which manifests proximally based, hypoplastic thumbs,¹⁴ disruption of *TBX5* causes Holt-Oram syndrome,¹⁵ whereas *SALL1* and *SALL4* mutations are associated with Townes-Brocks and Duane-radial ray syndrome.¹³

The signaling center associated with the dorsoventral axis, located in the dorsal ectoderm, produces a protein called Wnt-7a. This induces production of transcription embryology and classification factor *Lmx1* which is required for dorsalization of the limb.¹⁶ Once more, an activator inhibitor loop is generated by an additional transcription factor, produced on the ventral aspect of the limb termed *engrailed-1* (*En-1*) which blocks Wnt-7a expression.¹⁷ Wnt-7a also promotes *SHH* in the ZPA and thus has a role in both proximodistal and anteroposterior growth.

The normal development and formation of the thumb can be affected either during embryogenesis (fertilization to 8 weeks) or during fetal growth (8 weeks to birth). Even though the majority of mechanisms by which congenital differences of thumb development (and upper limb) occur are not known, most congenital differences are felt to occur during embryogenesis. These may result from chromosomal abnormalities, inborn errors of metabolism, infections, or teratogens.¹⁸ Subsequent necrosis of cells vital to the correct formation of the upper limb or delays in programmed cell death may then result in abnormalities of development (failure of formation: for example, in the fetus of a woman who has taken thalidomide^{19,20}; failure of differentiation: for example, syndactyly²¹). Following formation of the limb, abnormal rates of growth during the fetal period may result in hypertrophy (overgrowth: for example, nerve territory oriented macrodactyly) or hypoplasias (undergrowth: for example, brachydactyly). Congenital amputations seen in the amniotic band sequence (Streeter's dysplasia) occur late within the fetal period and are classified by pediatric geneticists as deformations of a normal hand plate that occur in utero. In

this sequence the secondary deformations to normal structures occur with changes in the uterine environment. Chromosomal and other inborn errors are designated as malformations. A disruption sequence occurs when normal tissue is subjected to an infection, or by vascular, mechanical, or metabolic toxins such as the sedative thalidomide, which was responsible for hypoplastic limbs five decades ago, primarily in Europe.²² Approximately 15% to 20% of thumb anomalies have a genetic chromosomal cause, most of which should be identified or mapped within the next decade. No more than 30% of the anomalies have known infectious, metabolic, or other identified causes, and for the largest group the cause remains unknown. A comprehensive exposition of the factors currently thought to be important in limb development can be found in reviews by Zeller et al²³ and Al-Qattan and Kozin,²⁴ whereas Oberg¹³ specifically considered thumb development.

Because of these developments, reappraisal of Swanson's classification of limb anomalies²⁵ is a logical progression of a greater understanding of limb development. Classifications based on the effects of specific genetic or molecular defects, such as that suggested by Tonkin et al,²⁶ are likely to become both more specific and complex as our understanding of this carefully choreographed process progresses. However, the chromosomal aberrations do not provide clear-cut pathways for the determination of clinical decision-making.

FREQUENCY

The frequency of congenital differences is subject to variation because of the genetic composition of the specific population being reviewed as well as discrepancies in nomenclature and sampling.²⁷⁻³⁰ Congenital differences involving the upper limb have been reported to occur in 1:200 to 1:626 live births. Entin^{31,32} observed that major congenital differences involving the thumb occurred in 16% of his series of congenital upper limb abnormalities. In 1977 Flatt³³ reported the frequency of hypoplastic thumb within his Iowa practice of congenital anomalies of the upper limb to be 3.6%. Lamb and colleagues,^{34,35} in their patients with 117 radial longitudinal deficiencies, found that there was variable penetrance and expressivity of thumb hypoplasia. Thumb hypoplasia is also associated with other hand anomalies and generalized syndromes involving the hematologic, musculoskeletal, cardiovascular and genitourinary systems. These are listed in Box 43-1.³⁶ Problems with small or inadequate thumbs are some of the most common encountered in congenital hand surgery, including hypoplastic thumbs seen in cleft hands, preaxial duplications, the constriction ring syndrome, clasped thumbs, retroflexed thumbs, five-fingered hands, and other diagnoses.³⁷ Therefore consultation with a genetic specialist is strongly recommended, and referral to standard genetics textbooks is a must for any responsible hand surgeon.

CLASSIFICATION

The classification of hypoplastic thumbs is presently determined by the clinical appearance of the affected thumb. The anatomic characteristics of the first ray form the basis of our current classification system. Before classification and management of a child with a hypoplastic thumb, a careful assessment includes the following:

- Size
- Position
- Relation to other fingers in the hand
- Osseous components
- Joint integrity
- Intrinsic and extrinsic myotendinous units
- First web space depth and width
- Associated hand anomalies

Box 43-1 Thumb/Radial Hypoplasia/Aplasia Associations**Thumb (T)/Radial (R) Hypoplasia/Aplasia**

Frequently seen in:

Aase syndrome (T, R)
 Baller-Gerold syndrome (T, R)
 Congenital microgastria-limb reduction complex (T)
 Deletion 13q syndrome (T)
 EEC syndrome (T)
 Fanconi syndrome (T, R)

 Seckel syndrome (R)
 Smith-Lemli-Opitz syndrome (R)
 Trisomy 13 syndrome (R)
 Trisomy 18 syndrome (T, R)

Metacarpal Hypoplasia

Frequently seen in:

CHILD syndrome (all)
 Coffin-Siris syndrome (all)
 Cohen syndrome (all)
 Deletion 18q syndrome (first)

Deletion 2q37 syndrome (all)
 Deletion 4q syndrome (first)
 Deletion 5p (cri du chat) syndrome (all)
 Diastrophic dysplasia (first)
 Duplication 10q syndrome (first)
 Duplication 9p syndrome (all)
 Dyggve-Melchior-Clausen syndrome (all)
 Grebe syndrome (all)
 Microdeletion 15q24 syndrome (first)
 Oto-palato-digital syndrome type II (all)
 Poland sequence (all)
 Short rib polydactyly, Majewski type (all)
 Tricho-rhino-phalangeal syndrome type I (all)

Occasionally seen in:

Brachmann-de Lange syndrome (first)
 Larsen syndrome (all)
 Multiple epiphyseal dysplasia (all)
 Robinow syndrome (all)
 Tibial aplasia-ectrodactyly syndrome (first)
 Triploidy syndrome and diploid/triploid mixoploidy syndrome (first)

Broad Thumb

Frequently seen in:

Aarskog syndrome
 Acromesomelic dysplasia
 Apert syndrome
 Carpenter syndrome
 Curry-Jones syndrome
 FG syndrome
 FGFR3-associated coronal synostosis syndrome
 Floating-Harbor syndrome
 Greig cephalopolysyndactyly syndrome
 Larsen syndrome
 Microdeletion 2q31.1 syndrome
 Oto-palato-digital syndrome, types I and II
 Pfeiffer syndrome
 Rubinstein-Taybi syndrome
 Saethre-Chotzen syndrome
 Simpson-Golabi-Behmel syndrome
 Weaver syndrome

Occasionally seen in:

Dubowitz syndrome
 Lenz microphthalmia syndrome
 Matthew-Wood syndrome
 Robinow syndrome
 Trisomy 13 syndrome

CHILD, Congenital hemidysplasia with ichthyosiform erythroderma and limb defects; *EEC*, ectrodactyly, ectodermal dysplasia, and clefting; *MURCS*, Müllerian duct hypoplasia/aplasia, renal agenesis, and cervicothoracic somite dysplasia; *VACTERL*, vertebral anomalies, anal atresia, cardiac defect, most often ventricular septal defect, tracheoesophageal fistula with esophageal atresia, renal abnormalities, limb abnormalities, most often radial dysplasia.

Complete evaluation of the osteoarticular column will require radiologic investigation. Even though primary ossification centers of the phalanges and metacarpal of the thumb appear in the second to fourth fetal months, abnormalities of the skeleton of the thumb, for example, triangular bones, may not be seen radiographically until well into the first or second year of life. In addition, secondary ossification centers within the epiphyses of the thumb normally appear between 13 months and 4 years of age.³⁸ The appearance of both primary and secondary ossification centers in a hypoplastic thumb is often delayed in proportion to the degree of hypoplasia. A delayed appearance should be expected in most thumb differences beyond type I³⁹ (Fig. 43-2).

Because there is a spectrum of thumb hypoplasia, accurate classification of the abnormality is required so that an appropriate management plan can be initiated. The current classification system that was proposed by Müller⁴⁰ and Blauth and Schneider-Sickert^{41,42} was expanded by Buck-Gramcko⁴³ in 1981 and defined five types of thumb hypoplasia and aplasia. This classification recognizes the progressive degree of hypoplasia from a slight size discrepancy, with all normal structures present, to total aplasia of the thumb. In 1995 Manske et al⁴⁴ proposed their modification of this system, dividing type III hypoplastic thumbs into IIIA and IIIB. This distinction is made by the presence (IIIA) or absence (IIIB) of a stable carpometacarpal joint (Box 43-2) and is very important in terms of management. These five types of thumb hypoplasia are

Fig. 43-2 Ossification times. Normal primary and secondary ossification centers of the hand are diagrammed with their times of radiographic appearance. At birth, primary ossification is present for the thumb metacarpal and phalanges. The secondary centers for the phalanges appear much later. Within the hypoplastic thumb or hand, the appearance of all ossification centers may be significantly delayed. There is also considerable variation between sexes and different populations.

Box 43-2 Classification of Thumb Hypoplasia**Type I: Mild Hypoplasia**

Minimal skeletal shortening
 Intrinsic muscle intact
 Extrinsic muscles intact
 Tendons intact

Type II: Moderate Hypoplasia

Moderate skeletal shortening
 Intrinsic muscle hypoplasia (median innervated)
 Small first web space
 Adducted thumb position
 MP joint instability

Type III: Severe Hypoplasia

Severe skeletal shortening
 Carpal hypoplasia
 Intrinsic aplasia (median) and hypoplasia (ulnar)
 Extrinsic tendon abnormalities
 Small first web space
 Severe MP joint instability

Type IIIA

Metacarpal very hypoplastic
 Carpals present
 CMC joint intact

Type IIIB

Proximal metacarpal aplasia
 Trapezium absent
 CMC joint absent

Type IV: Pouce Flottant (Floating Thumb)

Metacarpal absent; phalanges rudimentary
 Skin and neurovascular connection
 Intrinsic, extrinsic tendons absent

Type V: Aplasia

All structures absent

Type VI: Cleft Hand (Ectrodactyly)

Metacarpal, phalanges present
 First web syndactyly common; all degrees of syndactyly
 Deficient or absent adductor pollicis
 Thenar intrinsic (median innervated) present
 Skeleton hypoplastic
 Occasional thumb polydactyly

Type VII: Symbrachydactyly (Atypical Cleft Hand)

Central three rays most deficient; all degrees of hypoplasia to aplasia of index; long and ring rays; digits are often hypoplastic nubbins
 U-shaped cleft
 Flexor pollicis abnormal, often with intrinsic origin
 Ulnar-innervated intrinsic muscles to thumb are often absent
 Median-innervated intrinsics are usually present
 IP joint is stiff; MP joint is present and occasionally unstable
 Extrinsic flexor and extensor muscles are often weak
 Fifth ray is the best in the hand
 Hypothenar muscles intact

Type VIII: Thumb in Constriction Ring Syndrome (CRS)

Transverse amputation at level of:
 IP joint
 Proximal phalanx
 Metacarpal
 Anatomy proximal to amputation is normal
 Constriction rings (annular bands) at any level

Type IX: Thumb Hypoplasia in Polydactyly

Skeletal level and degree of complexity increases from distal to proximal
 Osteoarticular column is hypoplastic in biphalangal thumbs, higher than type IV (Wassel classification)
 Nail bed is smaller than normal in both partners
 Extrinsic tendons are shared
 Intrinsic muscles are present with abnormal insertions

Type X: Thumb Hypoplasia in the Five-Fingered Hand

Normal ray with metacarpal and three phalanges
 Absent thenar (median-innervated) intrinsics
 Normal digital intrinsics and extrinsics

Type XI: Short Skeletal Ray

Isolated or combined deficiency of metacarpal, proximal, or distal phalanges
 Collateral ligaments intact
 Triangular bones ("delta" phalanges) with longitudinal bracketed epiphysis are common
 ACS syndromes: Apert, Pfeiffer, Rubinstein-Taybi, and others
 Intrinsic muscles are intact, with abnormal insertions

commonly associated with radial (preaxial) dysplasia, and most congenital hand surgeons consider hypoplasia of the thumb with a normal radius as part of this spectrum. We have found it quite useful to correlate the degree of hypoplasia with the median- and ulnar-innervated thenar musculature (Fig. 43-3).

Hypoplasia of the thumb is also associated with many other congenital differences of the hand. Because the anatomic makeup of the thumb associated with these congenital conditions does not always allow easy categorization under the current classification system, we recognize six

Fig. 43-3 Thumb hypoplasia. **A**, The normal median-innervated intrinsic muscles (abductor pollicis brevis, flexor pollicis brevis/lateral head, and opponens pollicis) and ulnar-innervated intrinsic muscles (adductor pollicis, first dorsal interosseous, and flexor pollicis brevis/medial head) to a right thumb are illustrated. **B**, Within the spectrum of thumb deficiencies seen with radial dysplasias, all intrinsic muscles are present in type I thumbs and are severely hypoplastic or absent in type III thumbs. Only the ulnar-innervated adductor pollicis and the flexor pollicis brevis medial head are present and functional in hypoplastic type III thumbs. Rudimentary muscles may be present in type IV floating thumbs. The first dorsal interosseous muscle (also called the *abductor indicis* muscle), with its second metacarpal origin, is found only when the index digit is present.

other types of hypoplastic thumbs. These are associated with cleft hand, symbrachydactyly, constriction ring syndrome, radial polydactyly, five-fingered hand, and generalized syndromes with short, commonly angulated, osteoarticular columns, such as the acrocephalosyndactylies (see Box 41-2). Other authors consider most of these additional categories as either type I or II thumbs.

TIMING

As researchers and clinicians struggle with the possibilities of fetal surgery, many surgeons wonder whether they should be performing reconstructive procedures of the congenitally different hand as early as possible. Because the thumb accounts for 50% of hand function, early reconstruction of a hypoplastic or an absent first ray is certainly attractive so that the infant can develop with optimal cortical representation and use of the thumb. This ideal needs to be tempered with the knowledge that a congenital hand difference is in itself not a life-threatening condition (but may be associated with one), and the surgeon can use time to allow the affected part to grow, to observe its development, and to assess functional needs. A stable osteoarticular column of adequate length, mobile joints, growth potential, and an adequate, scar-free first web are the necessary requirements for performing surgery on a hypoplastic or absent thumb. If these requirements can be met, then with the use of magnification and adequate microsurgical skills, precise yet demanding surgical procedures can be performed on very young patients.

Many other factors need to be considered. Several arguments that are forwarded by the proponents of early surgery include the following^{37,45}:

- Anatomic: Release of tethered myotendinous units and joint contractures will help allow unrestricted growth, and anatomic adaptation of the reconstructed thumb will occur secondary to growth and functional use.
- Cognitive: Early surgery will allow the development of the child with a reconstructed thumb before thumb corticalization, which occurs at about 18 months of age.
- Psychological: Potential alleviation of anxiety in the parents and therefore the child.

These advantages of early surgery need to be weighed against those for delayed procedures, which include the following:

- The affected thumb is larger in size so that potential problems with osteotomies and fixation, joint reconstruction, and vascularity are reduced.
- A better assessment of the functional needs of the child can be performed.
- The child is potentially a more cooperative patient.

Reconstruction of the thumb should be completed by the time the child starts school so that maximal functional benefits can be achieved and the potential for ridicule by peers is minimized. In the absence of other organ system complications, we try to perform reconstructive procedures on hypoplastic or absent thumbs when the child is between 10 and 18 months of age. Pollicization at 1 year is often preceded by centralization or radialization of the hand and wrist between 5 and 8 months of age. In children with radial deficiencies and thumb aplasia of one upper limb and a less severe thumb hypoplasia on the opposite limb, surgeons should treat the stronger side, with the hypoplastic thumb, before attempting pollicization on the more deficient side. Because this hypoplastic thumb will be the child's best thumb, it is important to strengthen and improve it as soon as possible. However, parents often prefer to have the pollicization performed first and to have nothing done on the more complete side. Occasionally, simultaneous bilateral surgery is appropriate, for example, in a child with a type II thumb on one side and a contralateral type IV or V thumb.

The timing for correction of type IIIB deformities may be problematic. Although we believe pollicization is the procedure of choice, some parents and families simply will not allow it. We agree with other surgeons that the alternatives involve difficult reconstructions, often including two or more stages, and are wisely deferred until the child is 4 to 5 years of age, a time when the hand is larger and the patient may be more cooperative with the postoperative program.⁴⁶⁻⁴⁹

The determination of the optimal time to reconstruct a hypoplastic or absent thumb must be individualized in each patient. As these children may have other congenital anomalies associated with their thumb abnormality, it is important to assess these patients early in life so that a coordinated management plan can be formulated and instituted. Perhaps the most important variable is the confidence, surgical skill and experience of the surgeon and his team.

TYPE I THUMB HYPOPLASIA: MILD HYPOPLASIA

Anatomy

Type I represents the mildest form of hypoplasia within this group of congenital thumb differences. The thumb is slightly smaller but is normally configured (Fig. 43-4). The phalanges and metacarpal of the thumb can be slightly thinner than usual. The trapezium and scaphoid are present and the distal radius and styloid are not affected. The interphalangeal (IP), metacarpophalangeal (MP) and carpometacarpal (CMC) joints of the thumb are stable and exhibit normal passive and active motion. The intrinsic and extrinsic myotendinous units are present. The

Fig. 43-4 Type I thumb hypoplasia—mild. **A**, The skeletal ray is well segmented and may be short. All intrinsic muscles and extrinsic tendons are intact. First web space narrowing is minimal to moderate. **B** and **C**, Clinical and radiographic appearance of a child who did not require any surgical correction. Although his thenar muscles are weak, there are no significant functional problems.

median-innervated intrinsic muscles (flexor pollicis brevis [FPB]–lateral head, opponens pollicis [OP], and abductor pollicis brevis [AbPB]) can occasionally be mildly hypoplastic. The first web space may be slightly narrowed.

Management

These children are not usually functionally impaired. In fact, many children with type I thumb hypoplasia do not recognize anything abnormal about their hands. These thumbs are commonly found in patients who have a more severe radial dysplasia involving the contralateral upper limb. Children with type I hypoplasia have very little or no difficulty with key, pulp, or nail pinch, opposition, and grasping activities. Because functional problems are rare, surgical correction is not needed. Very occasionally a child with a type I hypoplastic thumb will require a release of a mildly contracted web (see Management under Type II Thumb Hypoplasia: Moderate Hypoplasia in this chapter). Any other procedures need to be precisely determined and planned to meet the functional needs of the patient.

TYPE II THUMB HYPOPLASIA: MODERATE HYPOPLASIA

Anatomy

Children with type II thumb hypoplasia have a moderate diminution in the size of the affected thumb (Fig. 43-5). The osteoarticular column is narrowed and short. The trapezium and scaphoid are present but may be small and may result in slight radial deviation of the hand. The distal radius has a normal configuration but may be short on occasion. Characteristic of type II thumbs is instability of the MP joint. This particularly effects the ulnar side of the joint with severe laxity of the ulnar collateral ligament (UCL). The IP and CMC joints are stable, but both may have some mild limitation of motion. The median-innervated intrinsic muscles are hypoplastic in contrast to the ulnar-innervated intrinsics, which are usually normal (see Figs. 43-4 and 43-5). This asymmetrical hypoplasia of the intrinsic musculature causes a dynamic imbalance on either side of the thumb. The stronger ulnar-innervated intrinsics, and in particular the adductor pollicis (AddP), adducts the thumb and contributes to a narrowing of the first web space. The degree of this deficiency is usually a reflection of the degree of hypoplasia of both the skeleton and the median-innervated intrinsics.

The pollex abductus deformity may be present and represents anomalous connections between the flexor and extensor tendons along the radial border of the thumb (Fig. 43-6). Uncommonly, a proportion of these patients will have absent^{50,51} or anomalous insertions^{47,52-55} of the flexor pollicis longus (FPL). The FPL or EPL tendon can also be in an aberrant position lying along the radial border of the proximal phalanx. When present, these tendons pass superficial to the hypoplastic thenar muscles, to which they are often connected. Distally the anomalous tendon usually inserts by two slips, one large slip into the volar-radial base of the distal phalanx and the other into the extensor pollicis longus tendon. The malpositioned FPL and/or EPL tendon functions as an abductor of the MP joint. Continued pinching activities associated with the anomalous FPL and the instability of the ulnar collateral ligament will result in radial deviation of the phalangeal portion of the thumb with concomitant adduction of the first metacarpal.

Other tendon anomalies seen with type II hypoplasia include eccentric insertions of extrinsic flexor and extensor tendons resulting in IP joint deviation, abnormal extensors,^{55,56} aplasia of the thenar muscles,⁵⁷ and occasionally anomalous muscles.^{54,58} Although the degree of hypoplasia seen with duplications, triphalangeal thumbs, cleft hand, symbrachydactyly, five-fingered hands, and so forth fall into the type II category, we have separated this large group of patients into individual categories for ease of anatomic analysis and consideration of treatment options.

Fig. 43-5 Type II thumb hypoplasia—moderate. **A**, There is minimal to moderate shortening of the skeletal ray. All bones are present and ligaments at the MP joint may be lax. The ulnar-innervated intrinsic muscles, AddP, and first DI (second metacarpal origin) are strong, and the median-innervated intrinsic muscles are very weak. Anomalous anatomy is common. Adduction contractures from fibrous structures and MP joint instability accompany a deficient first web space. **B-D**, Clinical appearance and radiograph of a child with type II hypoplasia of the right hand. The thenar intrinsic muscles are hypoplastic, the first web space is tight, and the thumb is much narrower than normal. Key pinch is weak, and the patient cannot hold heavy objects between the thumb and digits. In addition, the ulnar collateral ligament is weak at the MP joint.

Management

The problems that need to be addressed in children with type II hypoplasia are (1) narrowed first web, (2) instability of the MP joint, (3) poor palmar abduction (opposition), and, if present, (4) a lack of flexion of the IP joint. These problems can be managed surgically in one or two stages. Flatt³³ preferred to stabilize the MP joint and release the first web in an initial procedure, then restore opposition in a second procedure, whereas others prefer to reconstruct type II thumbs in one stage.³⁷ It is particularly important to avoid damage to the growth plates in any of the tubular bones of the thumb as any degree of growth arrest early in development will adversely affect the outcome of any reconstruction.

Fig. 43-6 Pollex abductus. **A**, In severe type II and many type III thumbs, there may be very little, if any, IP joint flexion, and there may be a radial deviation of the thumb at the MP joint because of the abduction force created by the combined action of the extrinsic flexor and extensor tendons joined by intertendinous connections, the pollex abductus. **B-E**, Within types II and III thumb hypoplasias (and proximal thumb duplications), a very wide spectrum of intratendinous connections may vary between a wide, loose, almost areolar band (*seen at top*) to a complete coalition of the flexor and extensor into a single tendon. With excursion from either the flexor or extensor side, the resultant movement in all these thumbs is abduction of the MP joint.

Narrowed First Web

The creation of an adequate first web space is of critical importance for the correction of any thumb anomaly and represents the most functional single correction in this group of patients. Normal thumb functions of key pinch, pulp and nail pinch, opposition, and thumb grasping maneuvers cannot be accomplished unless a good web space has been created. Many options for coverage are available and include various types of Z-plasty procedures, local flaps, local flaps with a full-thickness skin graft, tissue expansion, reverse-flow forearm island flaps, distant pedicle flaps, and free tissue transfer. Each of these procedures will provide different amounts and types

Fig. 43-7 First web space release—manta ray flap. **A-C**, The skin markings for the manta ray flap. **D** and **E**, The dorsal and volar fascia of adductor pollicis and the first dorsal interosseus muscles are released after the dorsal flap with the thumb and index extension have been raised. **F**, The dorsal flap is transposed to the volar surface and the markings of the volar flaps confirmed. **G**, Y-V advancement of the three limbs of the dorsal flap to widen the palmar web. **H**, Y-V dorsal advancement of the two volar flaps to release the dorsal web. **I**, Postoperative appearance; note the absence of palmar skin on the dorsum. This technique provides the best contour of all available methods of first web release.

Fig. 43-8 First web space release—four-flap Z-plasty. **A**, The skin markings have been made for a four-flap Z-plasty, including two 90-degree incisions perpendicular to the tight web between the thumb and index finger. Each is then bisected at a 45-degree angle. **B**, After the four separate flaps have been mobilized, reflected dense septal bands may be identified between the skin and muscle fascia, and larger fascial bands between the intrinsic muscle groups. **C**, Incision and excision of these bands may require dissection to the CMC joint level. **D**, Trimming and minor flap adjustments are always needed with the proper inset of the more mobile dorsal flaps with the more rigid palmar flaps. A skin redundancy on the radial side of the index finger has been eliminated with a straight extension. **E**, Dorsal view of the preoperative appearance. **F**, The postoperative contour is shown from the palmar surface.

of tissue for coverage and the surgeon is required to determine which procedure is appropriate for each patient. In children with type II hypoplastic thumbs, local procedures, particularly the four-flap Z-plasty or the manta ray flap,⁵⁹ are usually sufficient to provide adequate coverage of the web following soft tissue release (Figs. 43-7 and 43-8). In our experience the manta ray flap provides a greater percentage release of the first web when compared to the four flap Z-plasty.⁵⁹

Web Release

Despite the type of flap repair that the treating surgeon has chosen for the resurfacing of the first web space, the release of the web deep to the skin is the same. The incisions required for the particular procedure chosen are marked and incised. The flaps are elevated with subcutaneous fat and with preservation of large dorsal veins and sensory nerves. The spreading dissection progresses directly to the fascia overlying the first dorsal interosseous muscle. With skin flaps reflected, the tight fascia enveloping the first dorsal interosseous muscle and a second fascial band between it and the adductor pollicis muscle are incised parallel to the first metacarpal toward the

CMC joint. This release usually produces a dramatic improvement of the web contracture. The radial digital nerve and artery to the index finger need to be protected. A similar layer of fascia on the volar surface of the adductor pollicis is released if present. Within the depths of the web, the radial artery may be located passing from dorsal to volar between the two heads of the first dorsal interosseous muscle and should be preserved. Injury to paired venae comitantes accompanying these arteries may result in unnecessary bleeding. The fascial release is then assessed with abduction of the index finger and thumb. Skin and fascial release alone are sufficient to provide an adequate release on type II thumbs.

Occasionally, release of other structures is required. The tightest muscle is usually the first dorsal interosseous muscle (first DI), which can be released and recessed from distal to proximal along its thumb metacarpal origin. With the index finger and thumb held in abduction, the adductor pollicis (transverse head) can be visualized passing directly across the web to its insertion on the ulnar side of the thumb. Recession of this muscle can be accomplished either by step lengthening of its adductor aponeurosis or by direct myotomy of the transverse head. Our preference is to release the transverse head from the third metacarpal, but we refrain from incising this muscle unless absolutely necessary. Occasionally, anomalous muscles such as the musculus lumbricalis pollicis are found and should be excised.⁵⁸ The CMC joint in type II thumbs is rarely a site of joint limitation, but if an established contracture exists, as is occasionally seen in a late-presenting teen or adult patient, release of the ulnar ligaments should be performed. Occasionally, a CMC release will dramatically improve thumb circumduction and will unmask a minimal to moderate instability of the MP joint.

First Web Skin Cover Options

In a patient with type II hypoplasia, the deficiency of skin within the first web is mild. Because of this most patients can be managed with the use of a Z-plasty. Two-, four-, and five-flap Z-plasties have all been advocated for skin coverage of the first web following its release.⁶⁰⁻⁶² The principle in each type of Z-plasty technique is the same in that they all lengthen the contractual diagonal of the Z-plasty by transposing tissue perpendicular to it. Other options for first web space coverage include the manta ray flap, a transposition flap from the dorsal and radial side of the index finger, a transposition flap from the dorsum of the thumb with skin graft of the secondary defect, sliding flap from the ulnar side of the index,⁵⁰ or dorsal rotation/sliding flaps with or without skin grafts for the secondary defects.^{63,64} The use of tissue expansion⁶⁵ (see Fig. 43-13) and reverse-flow forearm flaps for coverage of the contracted first web in congenital hand anomalies has been described.^{66,67} These latter procedures are applicable to more severe degrees of thumb hypoplasia and will be discussed later.

Preferred Method

We prefer to use the manta ray flap, which produces the most aesthetic and contoured web (see Fig. 43-7) without volar skin being present on the dorsal aspect of the first web—the socially presented side of the hand. The manta ray flap is marked as shown in Fig. 43-7. The central V of the flap is marked at the midpoint of the web. The ulnar thumb and radial index flaps are then marked. The width of the base of these is determined by a pinch test to ensure closure. The two digital and midweb flaps are raised together and release of the underlying structures performed. The central dorsal V flap is advanced through the web to its position of maximal advancement on the palmar web skin. This point is marked, then the palmar skin incised and the dorsal V flap is advanced in a Y-V fashion and sutured into position. The ulnar thumb flap is transposed into the palm with its maximal point of advancement marked and similarly incised and inset. The same procedure is done for the radial index flap. The donor sites on the thumb and index are then closed.

Following transposition and advancement of these three flaps, two palmar flaps are created and then these are advanced dorsally in a Y-V fashion to obtain dorsal release. Care needs to be taken to ensure appropriate placement of these incisions so the width of the base of the central dorsal V flap is not compromised. After full release of the web, the flaps are transposed and the wounds closed with 5-0 or 6-0 mild chromic catgut, depending on the patient's age.

Other methods of first web space augmentation will be illustrated with the more severe forms of thumb hypoplasia.

Metacarpophalangeal Joint Instability

Type II hypoplasia is characterized by mild-to-moderate instability of the MP joint, especially of the ulnar collateral ligament (UCL), which needs to be stabilized to prevent radial collapse of the thumb at the MP joint during pinch. The paired radial collateral ligament (RCL) on the opposite side of the joint may also be lax but rarely causes functional sequelae. In very unstable joints very few if any fibers of a normal collateral ligament are present and the existing structure has the gross appearance of an attenuated joint capsule.

Options

The options available to reconstruct the UCL are as follows:

- Reefing of the lax ligament and ulnar joint capsule
- Proximal advancement of the UCL on the metacarpal (if there is not a distal first metacarpal growth plate)
- Tendon graft
- Tendon transfer using the ends of the transferred tendon as a graft
- MP joint fusion

The major proviso of all of the collateral ligament reconstructions is that the growth plate at the base of the proximal phalanx and condyle of the metacarpal head must not be damaged. Frequently the first metacarpal of the thumb has a double epiphysis, which should be preserved to facilitate potential growth of the deficient thumb. Metacarpophalangeal joint fusion is used only in patients near the end of their growth.

Preferred Treatment

The stabilization procedure chosen for the UCL in patients with type II hypoplasia depends on the patient's age. In children less than 3 years of age, reefing of the ulnar side joint structures is preferred with K-wire stabilization of the MP joint. Proximal advancement and plication of the UCL on the metacarpal is done in those without a distal metacarpal growth plate. A free tendon graft, either sutured into the periosteum or anchored intraosseously, is used in virtually all other patients. This procedure is usually combined with an abductor digiti quinti muscle transfer for restoration of palmar abduction or opposition^{68,69} (Fig. 43-9). Occasionally, the flexor digitorum superficialis (FDS) from the ring finger is used for this purpose, and when transferred, the UCL is reconstructed with the terminal end of this tendon as part of the transfer (Fig. 43-10). Joint fusion is reserved as a late procedure in patients who are virtually full grown, have had failed soft tissue reconstructive procedures, have an asymmetrical metacarpal head with joint deviation, and the very occasional older patient with degenerative MP joint changes.

Chondrodesis of the MP joint tends to be an unpredictable procedure.⁷⁰ Because total active and passive range of motion is decreased in these patients, preservation of joint motion is always preferred. In patients who have significant radial deviation of the MP joint, the flexor pollicis longus tendon may well be displaced radially, and if so, it will need to be repositioned or reconstructed, since this can lead to recurrence of the deformity.^{53,54} The symmetrical head is flattened on the radial side and is common in these children with the pollex abductus anomaly.

Fig. 43-9 Abductor digiti quinti muscle (ADQM) transfer for opposition. **A**, The radiograph of this type IIIA thumb shows a small web space and tightly adducted first metacarpal. **B**, The clinical photograph shows a marked deficiency of the median-innervated thenar muscles. The radial and ulnar collateral ligaments are stable. **C** and **D**, The ADQM is isolated on its origin from the pisiform and is passed through a subcutaneous tunnel above the palmar fascia to the radial side of the thumb. If two distal tendons can be dissected, separate insertions into the thumb are performed, one into the collateral ligament region and another onto the extensor mechanism. If one tendon is present, the preferred insertion is into the radial collateral ligament region. When a proximal dissection of the muscle is performed, its neurovascular bundle must be preserved. The muscle is seen here isolated on its neurovascular pedicle. **E**, The patient is seen 16 years later with functional palmar abduction from the muscle transfer.

Ulnar Collateral Ligament Stabilization

Following release of the first web, the ulnar side of the first MP joint is exposed. The dorsal sensory branches of the radial nerve to the thumb are retracted radially. Reefing of the attenuated ulnar collateral ligament and joint capsule can be addressed by either plication or by incision and closure of the lax structures with a “pants over vest” repair after dorsal-to-volar arthrotomy of the MP joint. The extensor mechanism with its attenuated shroud fibers is usually displaced radially and needs to be identified and mobilized from the dorsal joint capsule. The joint is held in full adduction and slight flexion with a single 0.028-inch K-wire. The ligament is then repaired with 4-0 or 5-0 nonabsorbable sutures. It is also important to tighten the attenuated dorsal capsule on the radial side of the joint. If not reefed snugly, relapse of the radial deviation of the thumb and subluxation of the proximal phalanx may occur.

Fig. 43-10 Thumb MP joint instability. **A**, The total absence of median-innervated thenar muscles and an unstable MP joint are characteristic of a type IIIA hypoplastic thumb. **B** and **C**, A well-segmented but flail joint is present. **D**, The superficial flexor tendon to the ring finger has been looped around the flexor carpi ulnaris and will be passed proximal to Guyon's canal toward the thumb. **E**, The transfer is secured tightly and both free ends are used to reconstruct the absent collateral ligaments. The *inset* shows the upper (cord) and lower (volar accessory) portions of the new radial collateral ligament. **F**, Three months postoperatively, the transfer is strong and the MP joint stable on both ulnar and radial sides.

Free Tendon Graft

Reconstruction of the UCL of the thumb MP joint with a free tendon graft in a child requires meticulous attention to detail so that the growth plates are not injured. Intraoperative radiologic assessment is essential to accurately place the tendon graft. The tendon graft is harvested from the ipsilateral palmaris longus; when this is absent, the choices are (1) contralateral palmaris longus, (2) plantaris, or (3) a toe extensor from one of the lateral three toes. The ulnar side of the MP joint is exposed and radiographs are taken of the thumb ray to determine the site of the metacarpal and proximal phalangeal epiphyseal plates. In a young child the tendon graft is sutured to the periosteum and is not passed through bone. This will minimize the risk of damage to the growth plates and prevent fracture of these slender bones. The tendon graft is first sutured to the proximal phalanx, away from its growth plate on its dorsoulnar aspect (at a point to mimic the insertion of the true collateral ligament). Next, the tendon graft is fixed to the volar-ulnar aspect

of the base of the proximal phalanx, again away from the growth plate (at a point to mimic the insertion of the volar accessory collateral ligament). Both ends are then brought proximally and sutured together to the dorsoulnar aspect of the metacarpal, again away from the growth plate. The configuration of the tendon graft will then best replicate the UCL.

In older children and adolescents with greater bone stock, the tendon graft can be passed intraosseously. Following exposure of the MP joint, the periosteum of the metacarpal is incised longitudinally proximal to the growth plate on the dorsoulnar surface. A transverse hole is then made large enough to accommodate the tendon graft. Minidrivers with pins are more precise than drills or gouges (see Fig. 43-9). In a small phalanx the tendon graft may need to be split to fit into a small hole in a slender bone. At the distal site in the metaphysis of the proximal phalanx, the periosteum is incised in a dorsopalmar direction. A hole is then made in the same direction, passing from the dorsal aspect of the phalanx to the palmar. The position of the two holes in the proximal phalanx should be such that they are replicating the insertions of the collateral ligament of the joint. The joint is then held with a 0.028-inch C-wire in full adduction and slight flexion. The tendon graft is then passed through the distal tunnel. Proximally the tendon graft is “ink-welled” into the gouge hole in the metacarpal with a transosseous pullout suture or small bone anchor. If a transosseous suture is used this is then tied over a button on the radial side of the thumb.

Arthrodesis or Chondrodesis

The cartilaginous surfaces of both the metacarpal head and the proximal phalanx are exposed through an incision placed dorsal to the midlateral line on the ulnar side of the joint. The cartilage is trimmed down to bleeding bone including the flattened radial side of the metacarpal. Small C-wires are used to position the joint in 20 degrees of flexion with adequate pronation to ensure pulp-to-pulp contact with the index finger. In adolescents and adults all cartilage is removed and a solid bone-to-bone fusion performed. In the adult age group, internal fixation can be used to produce a rigid osteosynthesis.

Opposition (Palmar Abduction) Transfers

The need for opposition transfers can be determined both by assessment of the position of the thumb and observation of the child at play. In a child with an inadequate abductor pollicis brevis muscle, the thumb is adducted with a narrowed first web space. When the child performs pinch tasks, he or she tends to use key pinching maneuvers, because the thumb cannot be abducted adequately to obtain pulp pinch. These children also may use two-handed grasp for larger objects, because they have difficulty with palmar abduction of their thumbs. The degree of first web contracture is a good clinical indicator of the degree of hypoplasia of thumb abductors.

Options

The transfers available for restoration of opposition include the Huber transfer^{47,68,69,71,72} (abductor digiti quinti minimi) or transfer of an extrinsic tendon; the most common being flexor digitorum superficialis to the ring finger.⁷³ (see Fig. 43-9; also see Fig. 43-17). The Huber transfer has the advantages of using a muscle of similar excursion and function to replace the abduction deficiency. It also has the advantage of recontouring the thenar eminence, which is deficient or flattened in these children. The use of this muscle for restoration of thumb abduction may mildly impair the cupping of the palm on the ulnar side of the hand. Some authors prefer the transfer of the flexor digitorum superficialis from the ring or long fingers.^{33,63,74} This transfer has the advantage of also providing tendon slips for UCL reconstruction and the limitation of not improving the contouring of the thenar region (see Fig. 43-10). Rarely, harvesting of an FDS tendon can

result in a swan neck deformity of the donor finger with a lax PIP volar plate or a flexion contracture of the same joint when the tendon has been harvested within zone II of the flexor sheath.

Preferred Method

The Huber transfer can be performed either separately or at the same time as the first web release and UCL reconstruction (see Fig. 43-9). If the transfer is completed in one stage, the first web should be released and the UCL reconstructed with the MCPJ stabilized with a pin, before transfer of the abductor digiti minimi. Our strong preference has been to release the first web space early in life and to delay the Huber transfer and stabilization procedure. At the time of muscle transfer to the radial side of the thumb, it is important to stabilize the ulnar side to counteract this potential deforming force.

Incisions for the transfer include a midlateral incision over the hypothenar eminence at the junction of the glabrous and nonglabrous skin. This incision passes from the metacarpophalangeal flexion crease of the small finger to the distal wrist flexion crease. If necessary, the incision is then extended radially in the normal skin crease at the level of the pisiform bone. In those with very tight skin over the deficient thenar region, a hypothenar skin ellipse can be included as a myocutaneous flap. A second high midaxial incision is centered over the radial side of the thumb MP joint. The hypothenar incision is made and flaps dissected off the muscular fascia. The abductor digiti quinti minimi muscle and its two insertions are identified. The insertion into the extensor mechanism on the ulnar side of the fifth finger is detached before the skeletal insertion into the base of the proximal phalanx. The muscle is then raised retrograde and separated from the more radial flexor digiti quinti muscle. Occasionally, no clear separation exists and both muscles must be raised together. This dissection progresses retrograde toward the pisiform. The neurovascular pedicle enters the muscle on its dorsoradial surface just distal to the pisiform bone and can be clearly identified with careful elevation. The origin of the abductor digiti quinti minimi may need to be released from the ulnar aspect of the pisiform if more length is required. This can be further elevated with a strip of flexor carpi ulnaris if required⁶⁹ (see Fig. 43-9, *C* and *D*). A very generous subcutaneous tunnel is then created for passage of the muscle (or muscles) from the pisiform to the incision on the radial side of the thumb. The muscle is then passed through this tunnel, and both tendons are then reinserted. The shorter tendon from the proximal phalanx is sutured to either the base of the thumb proximal phalanx or radial joint structures, and the longer tendon is interwoven into the extensor mechanism of the thumb. The tunnel must be adequate to allow for postoperative swelling, and the thumb ray must be positioned in full palmar abduction to relieve excessive tension on the transferred muscle tendon unit.⁷¹ The surgeon also has the option of raising this muscle as a myocutaneous flap and placing the skin portion in the lower half of the thenar eminence. In patients with a lax UCL, we prefer to attach the transfer to either the metacarpal head or the radial collateral ligament structures instead of the proximal phalanx.

Interphalangeal Joint Flexion

Although most patients with type II hypoplasia of the thumb have impairment of IP joint flexion, only a few require flexor reconstruction, because the total active range of motion in these patients following web release, MP joint stabilization, and opponensplasty is usually functionally adequate. The ulnar nerve-innervated medial head of the flexor pollicis brevis usually provides strong MP flexion and IP extension. Repositioning the extrinsic extensor of the thumb is required in patients with severe radial deviation of the MP joint, combined with a radially displaced long flexor. The connections between the extrinsic flexor and extensor tendons forming the pollex abductus anomaly are common in this situation and need to be released.⁵⁰⁻⁵² Both of these anomalous tendons are encountered more commonly in type III hypoplasias.

TYPES IIIA AND IIIB THUMB HYPOPLASIA: SEVERE HYPOPLASIA

Anatomy

With type III hypoplasia there is a greater reduction in the size of the thumb, and commonly the origin of the base of the thumb is displaced distally. The distinction between types IIIA and IIIB is made on the presence or absence of the proximal portion of the first metacarpal and a CMC joint⁷⁵ (see Figs. 43-11, 43-13, 43-17, and 43-18). This difference represents a more severe deformity along the continuum of thumb hypoplasia. The length of the osteoarticular column is shorter in type III. The metacarpal is more severely affected than the phalanges and there is an absence of the proximal portion of the metacarpal in type IIIB thumbs.

The radial carpal bones are commonly hypoplastic. The trapezium in type IIIB is usually absent. The distal radius is usually normal in size but the radial styloid process may be absent. The MP joint is completely unstable. The CMC joint is present but hypoplastic in type IIIA and absent in type IIIB. Commonly, there is aplasia of the median nerve-innervated intrinsic muscles and moderate-to-severe hypoplasia of the ulnar-innervated intrinsic muscles: the adductor pollicis and deep head of the flexor pollicis brevis (Fig. 43-11). The radial origin of the first dorsal interosseous from the thumb metacarpal is more severely affected than that from the index metacarpal. The radial head is usually hypoplastic. In many children with type IIIB thumbs it is absent. Extrinsic myotendinous abnormalities are more common than normal anatomy. The FPL can be displaced radially so it acts as an abductor of the MP joint and produces minimal flexion of the first ray, resulting in the so-called pollex abductus.^{47,52} The associated flexor retinaculum of the thumb is poorly developed with either attenuation or absence of the major pulleys of the thumb.

Interconnections between the FPL and the extrinsic extensor are common and contribute to both radial deviation and limitation of IP joint flexion. These radially displaced tendons often attach to anomalous proximal muscle bellies within the palm and do not extend to the normal origin in the forearm. More commonly, the FPL is absent.⁵⁰ Aplasia of the FPL can usually be determined by the presence of some passive IP joint flexion without any active flexion, coupled with an absence of a palmar flexion skin crease at the IP joint level. The long extensor of the thumb and the outcropping muscles (AbPL and EPB) may be absent in type IIIB. The first web is severely constricted.

Management

The management of patients with type III hypoplasia remains controversial. The quandary is one of reconstruction of the deficient IIIB thumb versus ablation and pollicization of the index finger. Cultural, racial, and parental expectations together with the surgeon's experience all play a part in the decision-making process. Reconstruction of all type III thumbs will require:

- First web release and coverage
- Stabilization of the MP joint
- Restoration of opposition
- Extrinsic tendon transfers for extrinsic deficiencies

As a general rule, children with type IIIA thumbs do better with a reconstruction and those with type IIIB thumbs are best treated by pollicization, but factors such as race and cultural beliefs may determine the course of treatment in an individual patient.

Although short, these thumbs are usually of sufficient length to be functionally adequate. Since the advent of free joint transfers, surgeons who are skilled in microsurgical techniques can successfully reconstruct the basal joint of the thumb (see Fig. 43-22). Unfortunately, this procedure does not simulate a normal CMC joint, because a transferred metatarsophalangeal joint of the second toe can only provide motion in a single plane. In addition, extensive tendon transfers

Fig. 43-11 Type IIIA thumb hypoplasia—severe. **A**, These thumbs exhibit more severe skeletal hypoplasia, including the carpal bones. Median nerve-innervated thumb intrinsic muscles are severely hypoplastic or absent, and the ulnar-innervated muscles are present but weak. Extrinsic tendons are abnormal, the “pollex abductus” deformity is frequent, the first web space is small, and the MP joint is unstable (more on the ulnar than the radial sides). The CMC joint and thumb metacarpal are intact in IIIA thumbs. **B-E**, Clinical photographs and a radiograph showing a short, slender metacarpal, an intact CMC joint, severe hypoplasia of the thenar eminence, and a lax MP joint. The absent IP flexion crease is indicative of a deficient or absent FPL

are still required for motion at the MP and IP joints. Those children who have multistaged reconstructions of type IIIB thumbs will also require joint stabilization at one or more levels. More recently, a hemimetatarsal transfer has been described for reconstruction of type IIIB thumbs.⁴⁹ The usual treatment plan for these patients with the more severe type IIIA deformities is to perform the web release and MP joint stabilization as the first stage. Restoration of opposition is then completed as a second procedure with additional extrinsic tendon transfers being done at the same time or as required in additional stages.

Narrowed First Web and MP Joint Instability Options

Release of the contracted first web in patients with type III thumbs is the same as that described for type II hypoplasias. In types IIIA and IIIB the severity of contracture of the first web will determine the type of skin coverage procedure required. Although many children with type III

thumbs are successfully treated with either a four-flap Z-plasty (Fig. 43-12) or a manta ray flap (see Fig. 43-7), those with more severe constriction of the first web need more tissue. Local flap options include: the sliding flap from the ulnar side of the index,⁷⁶ dorsal rotation/transposition flaps with or without skin grafts for the secondary defects,⁶⁴ tissue expansion^{37,65} and reverse-flow forearm flaps⁶⁷ or free tissue transfer.⁷⁷

Stabilization of the MP joint may only require UCL reconstruction. In most patients there is laxity of both collateral ligaments, with the UCL being more affected than the radial collateral ligament (RCL). Construction of the UCL takes precedence but occasionally both ligaments may

Fig. 43-12 Type IIIA reconstruction. **A**, The preoperative appearance of both hands in a youngster born with short stature and floppy thumbs. The thumbs are flail at the MP joint, adducted, and there are no median-innervated intrinsic muscles. **B**, The gross instability at the MP joint precluded any functional pinch. **C** and **D**, At surgery a pollex abductus anomaly was found. After release both collateral ligaments were reconstructed with autogenous tendon grafts anchored into bone. The ulnar collateral ligament of the MP joint is seen on the right. **E** and **F**, The first web space has been released with a four-flap Z-plasty at the same time as an ADQM transfer (Huber). **G**, Buddy taping of the index and long digits was necessary postoperatively to get this child to actively incorporate the use of his new thumbs. The facies of this child is typical of those with associated Fanconi anemia.

require construction. This can be accomplished with the techniques described above in type II hypoplasias. If both collateral ligaments require reconstruction, the same choices are available:

- Reefing of the lax ligaments and joint capsule
- Proximal advancement of the RCL and UCL on the metacarpal
- Tendon graft either as a free procedure or being
- Incorporated as part of a tendon transfer; for example, flexor digitorum superficialis (FDS) from the ring finger, to restore opposition
- MP joint chondrodesis⁷⁰ or arthrodesis; stabilization by chondrodesis or arthrodesis may affect growth in the young child

Preferred Method

In the more severe cases of first web contracture, where coverage cannot be achieved with local procedures, soft tissue coverage is provided by the importation of distant tissue. This can be done with the use of reverse flow island flaps from the forearm or using microvascular free tissue transfer. Both the radial forearm and dorsal interosseous island flaps have been used in congenital hand surgery.^{67,78,79} If a forearm flap is used, the radial forearm flap is preferred, because it is a more robust flap^{80,81} (Fig. 43-13). Because children with preaxial deficiencies may have anomalies

Fig. 43-13 Type IIIA reconstruction with a radial forearm flap. **A**, Preoperative clinical appearance and radiograph showing a small thumb ray with an intact CMC joint and no first web space. **B** and **C**, The angiogram shows a three digits and one thumb hand with communication between the radial and ulnar portions of the hand. **D**, A distally based radial forearm vascular island flap has been passed through a generous subcutaneous tunnel into the defect created by release of the soft tissue between the thumb and index digits. This flap in young children contains a large amount of subcutaneous fat, which cannot be debrided. **E**, There is good perfusion after a tension-free inset into the new web space. **F**, One year later, the first web space has been well maintained by this full-thickness flap.

Fig. 43-14 Technique for elevation of a groin flap. **A**, Skin markings for the flap are drawn based on the axis of the superficial circumflex iliac artery (SCIA), which runs parallel and inferior to the inguinal ligament. **B**, A skin island is designed to permit primary closure of the defect. **C**, Elevation begins laterally in a suprafascial plane. **D**, At the lateral border of the sartorius muscle, the plane of dissection deepens to include elevation of the deep fascia. The SCIA can be visualized through the fascia. **E**, The vessels are dissected to their origin from the common femoral artery and the femoral vein (occasionally the superficial circumflex iliac vein originates from the deep circumflex iliac vein). Flap perfusion should then be assessed, because a prominent superficial venous system mandates additional anastomosis to augment outflow of the medialmost skin.

of the radial vasculature, preoperative angiography of the forearm and palmar arches is essential. When the palmar arches are incomplete, the radial forearm option cannot be used.

If the treating surgeon is experienced with pediatric microsurgical techniques, the use of free tissue transfer is an excellent choice for resurfacing the first web in these children. Our preferred transfer is the groin flap because of its donor site and relative thinness. The radial artery is the usual arterial recipient and a dorsal vein for the venous anastomosis (Fig. 43-14). Sliding and rotation flaps from the visible dorsal portion of the hand with skin grafts in the donor region are popular with many surgeons, but may produce unacceptable scarring on the socially presented surface of the hand. Dorsal skin expansion is another option for those experienced with these techniques⁶⁴ (Fig. 43-15).

Fig. 43-15 Skin expansion for the first web space. **A**, This 10-year-old child with type IIIA thumb hypoplasia lacks any stability with pinch as a result of an attenuated ulnar collateral ligament. A Huber transfer performed earlier in childhood pulled the thumb into radial deviation. **B**, The radiograph shows a 90-degree deviation at the MP joint. **C**, An inadequate arterial communication between the radial and ulnar sides of the hand ruled out a distally based forearm flap reconstruction of the first web space. **D**, Dorsal skin has been expanded over a 4-week period. **E**, This skin was advanced to provide adequate coverage. At the same time, the ulnar collateral ligament was reconstructed with both local tissue and a free tendon graft. **F**, Following reconstruction, the patient has a stable MP joint and a wide first web space lined by full-thickness tissue.

The thumb-index web space is released with a longitudinal skin incision centered over the middle of the web on both the palmar and dorsal surfaces. This incision will adequately expose the UCL of the MP joint. A separate radial midaxial incision on the other side of the thumb is required to reconstruct the radial collateral ligament (RCL). In young children we often choose to simply imbricate the collateral ligaments of the MP joint. In thumbs in which the UCL is more severely affected than the RCL, a tendon graft of the UCL with imbrication of the RCL and dorsal capsule is a good option. Bilateral tendon grafts are rarely used but may be required in very severe cases. Chondrodesis is another option. Following MP joint reconstruction the MP joint is held in position with a 0.028-inch C-wire for 3 weeks. A second larger threaded C-wire may be needed transversely between the first and second metacarpals to hold the released ray abducted and pronated. Individual pins attached to an external fixation device will accomplish the same (see Fig. 43-15).

Following release of the web, a diamond-shaped defect is created. A template is made of this defect and transferred to the groin, or the volar forearm overlying the course of the radial or the dorsal proximal forearm over the posterior interosseous artery, which has been mapped out by Doppler examination before tourniquet inflation. If a forearm flap is being used, the pivot points for the radial forearm and dorsal interosseous forearm flaps are the radial styloid and the proximal edge of the extensor retinaculum, respectively. The choice of which flap is determined before the surgery with the use of angiography. It is important to elevate both of these flaps with a 1.5 to 2.0 cm cuff of fascia beyond the skin paddle, because in this young age group cutaneous perforating vessels to the skin flap can be quite tenuous. The flaps are raised retrograde by routine methods, as previously described^{67,78-82} (see Fig. 43-13). No attempt should be made to thin these flaps before inset, because this can jeopardize their vascularity. The flaps are tunneled into the defect while directly observing the pedicle, which cannot be kinked or rotated. The flap is inset using 5-0 and 6-0 mild chromic catgut, with the forearm wound being closed with a subcuticular suture. If arterial flow is sluggish after the tourniquet is released, the flap may be “supercharged” by a direct arterial anastomosis to the radial digital artery of the index finger.

When using a free groin flap, the surgeon needs to consider the harvest site to avoid future hair growth on the flap.⁷⁷ The flap is raised in a retrograde fashion (see Fig. 43-14). Meticulous technique is required to avoid damage of the vasculature to the flap. Intimate knowledge of the anatomy and anatomic variations is required. The size of the SCIA in young children is less than 1 mm, and this technique should only be undertaken by experienced pediatric microsurgeons (Fig. 43-16).

Opposition Transfers

In patients with type IIIA and IIIB thumb hypoplasia, the preferred method for restoration of opposition or palmar abduction is the Huber transfer (see type II opposition transfers). Occasionally, in older children and adolescents, the use of an FDS tendon is quite practical, because this method provides simultaneous opposition transfer and collateral ligament reconstruction. In thumbs with severe laxity of both collateral ligaments of the MP joint but only mild first web contracture, a single-stage procedure can be performed: web release with a manta ray flap (see Fig. 43-7), and FDS transfer for opposition (Fig. 43-17). If there is severe instability of both sides of the MP joint associated with a very contracted first web, a two-stage procedure is preferred: web release with distant flap reconstruction with a free groin flap (see Fig. 43-16) or reverse-flow forearm flap repair, followed by FDS transfer with bilateral ligament reconstruction.

Harvest of the FDS tendon to the ring finger is done through a transverse incision in the distal palmar skin crease. The A1 pulley of the ring finger is decompressed and the FDS tendon identified. With the ring finger pulled into flexion, a right-angle retractor is used to pull the FDS

Fig. 43-16 A child with thumb/finger polysyndactyly, with first web syndactyly treated with bilateral free groin flaps. **A**, Preoperative appearance, and **B**, radiologic findings. **C**, Intraoperative release of the first web. **D**, Bilateral groin flaps planned. **E**, Groin flap inset into right first web. **F**, Postoperative appearance of the hands.

Fig. 43-17 FDS dual transfer. The preferred technique for individuals with flail thumbs lacking good thenar muscles is the transfer of the ring flexor digitorum superficialis to the radial side of the thumb. The tendon is passed from whatever direction the surgeon chooses from the forearm. One slip is passed through a gouge hole proximal to the metacarpal head, and the tendon is secured tightly. The two tendon slips can then be used for construction of collateral ligaments on both sides of the joint.

proximally. Both slips of the FDS are incised as distal as possible. Through a longitudinal incision on the radial side of the flexor carpi ulnaris (FCU), the disconnected FDS tendon is delivered. The tendon should not be allowed to desiccate beneath the hot lights. A pulley is then constructed from part of the FCU and a generous subcutaneous tunnel is made from the wrist incision to a radial midlateral incision centered over the MP joint of the thumb.

We have encountered secondary ulnar nerve compression neuropathies when the transfer has been directed through Guyon's canal. The tendon is then tightened and split longitudinally to a point at which the full tendon meets the radial side of the metacarpal head. In patients with enough diaphyseal bone, the radial slip of the FDS tendon is passed through the metacarpal head to the ulnar side of the joint, which has been exposed through the first web release incision or through a midlateral incision. The UCL is constructed with one slip and the RCL with the other.

Attenuated sagittal fibers of the extensor mechanism and dorsal capsule are imbricated and tightened at the same time. Before both slips of the FDS are completely sutured in place, it is important to assess the motion of the MP joint so that the tendon grafts do not restrict this motion. Since these reconstructed ligaments loosen with time, increased tension and decreased motion are preferred initially.

Interphalangeal Joint Motion

The majority of patients with type III hypoplasias of the thumb lack IP joint flexion as a result of hypoplasia or aplasia of the flexor pollicis longus myotendinous unit. This anomaly gives these thumbs their characteristic slender appearance and associated lack of flexion creases. In this group it is unusual to have absence of both the FPL and the deep head of the FPB, which usually accounts for some thumb flexion. Tendon transfer for IP joint flexion should only be done in patients who have greater than 30 degrees of passive IP joint flexion and a stable joint.

The absence of both short and long flexors (FPB and FPL) will severely impair both pinch and grasping functions. In patients who do not have the pollex abductus deformity, the pulley system is significantly attenuated, but the FPL tendon is usually more developed. Transfer of aberrant tendons into normal positions should not be done, since these tendons are commonly connected to poorly developed proximal muscle bellies. The results of these transfers are predictably poor.

Reconstruction of type IIIA thumbs that lack IP joint flexion is best accomplished in two or more procedures. In a patient with the pollex abductus anomaly, the abnormal FPL is divided and any flexor-extensor interconnections released at the time of first web release and MP joint stabilization. The FPL tendon is then reinserted into the base of the first metacarpal to function as a long abductor of the thumb. Pulley reconstruction will be required before transfer of ring or middle finger FDS and can be done at the next stage, in conjunction with the Huber transfer for opposition. The distal portion of the malpositioned FPL can be used for pulley reconstruction. The placement of a silicone tendon rod at this stage produces a tunnel for the ensuing tendon transfer. Transfer of the FDS tendon for FPL is then done at a third stage. In patients who have aplasia of the FPL but a reasonable pulley mechanism, restoration of active IP joint flexion can be performed by transfer of an FDS tendon at the same time as the Huber transfer.

Thumb extension may also be absent in the more severe thumb hypoplasias. The extensor indicis proprius is usually available for transfer. Commonly there is a satisfactory distal extensor tendon present, which can be used and obviates the need for a tendon graft. If this is also absent then an extensor communis tendon can be used and, following transfer, thumb extension will occur simultaneously with digit extension. Other transfers such as FDS to EPL, brachioradialis or extensor carpi radialis longus plus a tendon graft to EPL can be considered. The reconstruction of those thumbs with absent extrinsic extensors follows the same algorithm as that for the treatment of the clasped thumb.⁸²

TYPE IIIB THUMB HYPOPLASIA

Options

The management of type IIIB hypoplastic thumbs is more controversial. Reconstruction in these patients will require multiple procedures, including stabilization of the base of the thumb ray. These thumbs are diminutive, usually arise quite distally in the hand and have multiple intrinsic and extrinsic deficiencies (Figs. 43-18 and 43-19). Because of the size of the thumb, reconstruction may appear to be an attractive option. Many parents are often reluctant, some strongly insistent, about considering any option other than reconstruction. In any reconstruction of a type IIIB thumb, the surgeon must be able to provide a mobile, stable thumb of sufficient length and to preserve growth potential with functional intrinsic and extrinsic myotendinous units and an

Fig. 43-18 Type IIIB thumb hypoplasia. **A**, The median nerve–innervated thenar intrinsic muscles are absent entirely. There is severe hypoplasia of the AddP, the FPB-lateral head, and the ulnar origin of the first DI. The CMC joint articulation of the proximal metacarpal is absent. The MP joint is very lax or absent on both radial and ulnar sides. Flexor and extensor extrinsic tendons are severely hypoplastic or absent. **B-D**, Clinical appearance and radiograph of a 4-year-old patient with a well-formed but functionless floppy thumb. There is no skeletal stability or extrinsic flexion or extension. Very small flexor or extensor tendons may be present and can result in some movement.

Fig. 43-19 Spectrum of metacarpal and CMC deficiencies. **A-D**, There is no arbitrary distinction between specific categories of thumb hypoplasia based on the skeletal appearance alone. These thumbs, which show varying degrees of hypoplasia with a presumably intact CMC joint, would be classified as type IIIA. **E-H**, The smaller metacarpals in these examples would signify type IIIB thumbs. **I-L**, These thumbs, with no skeletal connection, would be classified as floating thumbs, type IV. When a tight syndactyly exists between the thumb and index digit, an associated congenital heart defect (Holt-Oram syndrome) may be present.

Fig. 43-20 Bypass of use of the thumb in preference for second web space grip.

Fig. 43-21 Type IV thumb construction. **A** and **B**, The preoperative radiograph and clinical appearance of a type IV thumb in a child whose parents insisted on saving it. **C** and **D**, A bridging iliac corticocancellous bone graft was used to stabilize the thumb, which became an immobile post and did not grow commensurately with the child. At 14 years of age, the patient came to our clinic and asked when I would give her a “normal” thumb.

adequate scar-free first web space. Unfortunately, it is common for reconstructed thumbs in these patients to be stiff and unaesthetic, and the reconstructed thumb will still be bypassed in preference to the index finger. Observation of the child at play will usually direct the surgeon and family to the best course of management (Fig. 43-20). A child who bypasses the hypoplastic thumb before reconstruction will usually continue to do so after reconstruction.

Staged Reconstruction

The order of procedures in the reconstruction of type IIIB hypoplastic thumbs is (1) stabilization of the thumb osteoarticular column combined with first web release, (2) MP joint stabilization and opponensplasty, and (3) staged extrinsic tendon transfers as required, FDS for FPL and EIP for EPL. Adductorplasty may also be required (Fig. 43-21).

Using microvascular free tissue transfers, surgeons now have the ability to transfer joints with the growth plates of the accompanying bones. The procedure of choice for stabilization of the base of the flail-type IIIB thumb is the transfer of the metatarsophalangeal joint of the second toe (Fig. 43-22). Dorsal skin with veins is included for augmentation of the thenar region. The toe MP joint is positioned in hyperextension at the base of the thumb with a small portion of the distal diaphysis with the metatarsal head. Following this microvascular transfer, the reconstruction is similar to that described previously for a type IIIA hypoplastic thumb. Other options for the type IIIB thumb exist. Hemimetatarsal transfer of the second metatarsal⁴⁸ or a nonvascularized iliac crest graft may be used to provide a nonmobile strut connected to the base of the index metacarpal; however, iliac crest used as a bone graft may resorb, will not grow, and is not recommended.

Rarely, a type III thumb may present with absence of the diaphysial portion of the metacarpal and an intact CMC joint. In this instance an intercalated iliac crest bone graft is the treatment of choice. Despite limitations, staged reconstructions of type IIIB thumbs may result in high parent and patient satisfaction. Long-term follow-up of a limited number of these patients reveals limited function in patients who are nevertheless very enthusiastic about their thumbs.

Preferred Management

Even though cultural and parental beliefs can provide great pressure for reconstruction in this group of patients, we believe that a well-executed pollicization of the index finger will provide a superior result to staged reconstruction. We have had adequate experience with both methods. This recommendation is of greater significance for the bilateral deformity.

TYPE IV THUMB HYPOPLASIA: POUCE FLOTTANT

Anatomy

Pouce flottant is the French term for “floating thumb.” Such thumbs arise distally from the palm and usually lie along its radial midaxial border. These diminutive thumbs are attached to the hand only by a soft tissue pedicle, which has been described by Littler⁸³ as “nature’s own neurovascular pedicle” because of the presence of a single digital nerve and artery within the skin bridge (Fig. 43-23). These thumbs do not have a metacarpal bone. One or two small phalanges tend to be present within the soft tissue envelope of the thumb. If two phalanges are present, the IP joint does not have passive motion. The intrinsic muscles to the thumb are absent, as is the radial head of the first dorsal interosseous muscle. The ulnar origin of the first dorsal interosseous muscle is usually present, and this muscle functions as an abductor indicis.

Occasionally, motion is seen in a *pouce flottant* because of the presence of very rudimentary tendon units passing into the hypoplastic digit. Exploration of these thumbs reveals fascial slips passing through the pedicle that merge with the fascial bands within the floating digit. Within the carpus the trapezium is absent, and less commonly, the scaphoid. The trapezoid may be hypoplastic. The radial styloid may be absent, but the distal end of the radius is normal in most of these children.

Management

The best reconstruction for type IV thumbs is ablation and pollicization of the index finger. The larger variants of type IV thumbs with skin bridges of 1.0 cm or larger often have well-developed thenar intrinsic muscles that are quite effectively transferred to improve both palmar abduction and adduction of the pollicized index ray.

Staged construction of a thumb using the pouce flottant has been described using the methods outlined for reconstruction of a type IIIB and IV hypoplastic thumbs.^{49,84} The final results of these staged procedures are comparable and often the salvaged pouce flottant is stiff, immobile and “gets in the way” in an abducted position from the rest of the hand (see Fig. 43-21). Stability can be obtained but motion is severely impaired. Because these thumbs are small and have a rudimentary nail complex, the constructed thumb will definitely be less aesthetically acceptable than a pollicized index finger.

TYPE V THUMB HYPOPLASIA: APLASIA

Anatomy

In type V there is absence of the thumb osteoarticular column and the associated intrinsic and extrinsic myotendinous units. There is aplasia of the radial origin of the first dorsal interosseous muscle and in 50% of cases the entire muscle is absent (Fig. 43-24). The trapezium and commonly the scaphoid are aplastic, with the trapezoid being hypoplastic, and the collective carpal hypoplasia results in a radial deviation of the hand and wrist. The radius may be normal, hypoplastic, or absent. When the radius is present, the radial head is often subluxed or dislocated at the elbow level. With aplasia of the thumb the index finger tends to “autopollicize” (see Fig. 43-24). The pulp of the index finger widens and the digit pronates and sits in an abducted position resulting in a widening of the intermetacarpal space and attenuation of the intermetacarpal ligament. At best this is a poor substitute for normal key pinch and thumb index grasping maneuvers.

In more severe degrees of radial dysplasia (preaxial failure of formation) the index finger may also be hypoplastic, joined to the long finger by an incomplete syndactyly, and demonstrates markedly reduced active and/or passive range of motion at the MP, PIP, and DIP joint levels. With associated hypoplasia of the radius, the index and long fingers are rarely normal.

Management

With severe hypoplasia (types IIIB and IV) and aplasia (type V) of the thumb, the preferred treatment is pollicization of the index finger. Although reconstruction of these diminutive thumbs is feasible and preferred in some societies because of the importance placed on a full complement of fingers, we think a well-executed pollicization will predictably result in a more functional and aesthetic thumb.

Pollicization

Gosset⁸⁵ and Hilgenfeld,⁸⁶ working independently, designed methods of transposition of the index finger into the thumb position. All of their cases involved posttraumatic deformities in which the proximal thumb metacarpal and CMC joint were intact. Littler⁸⁷ studied their work, refined their techniques, developed new incisions, and expanded their basic concept to include the congenitally absent thumb. His unique and detailed drawings popularized the concept of index transposition among hand surgeons. Buck-Gramcko^{88,89} in Germany contributed further refinements during an extensive experience with radial dysplasias associated with the thalidomide crisis in western Europe and elevated this operation to its present status.

Although pollicization greatly enhances the function of these hands, it is important to remember that the index finger is only placed in a more strategic position to simulate a thumb. The newly created CMC joint was the index MCP joint and therefore does not have the same degree of freedom as the normal CMC joint of the thumb.

Fig. 43-24 Type V thumb hypoplasia. **A-C**, With complete aplasia, no thumb structures are present. In approximately half of these patients, the radius is normal. The trapezium, trapezoid, and scaphoid carpal bones are often hypoplastic and a strong first DI (abductor indicis) pulls the index digit in abduction and in as much pronation as the intermetacarpal ligament will allow. **D-F**, Index digits, which are not abducted, are often stiff at the interphalangeal joints and are commonly associated with some degree of radial hypoplasia or aplasia. The amount of stiffness decreases from radial to ulnar digits. Accordingly, the ring and small fingers are always the most functional components of these hands.

Timing

There is no consensus on the best age at which to perform a pollicization. We have performed this procedure as early as 4 months of age and as late as 15 years of age. Those in favor of early surgery feel that because the child develops thumb awareness by 3 months of age and prehension by 1 year, it is important to place the index finger in the thumb position by 1 year so the child can develop a “thumb.” There is no cortical representation of the absent thumb, and the index finger is the most radially represented digit in the cortex. Therefore early surgery will take advantage of “cerebral plasticity” and help obviate the need for the child to “relearn” using the newly positioned index finger. Edgerton et al⁴⁵ suggested that early surgery is also advantageous to the developing child’s body psyche, because a child is aware of his or her hands early, and corrective surgery may lessen the perception of an unfavorable body image. Proponents of late

surgery feel that with a larger hand and less subcutaneous fat, a much more precise procedure can be accomplished. The timing of pollicization needs to be determined by the treating physician, because performing this technically demanding surgery on small hands requires meticulous attention to detail and technique. The tyro in hand surgery with limited experience is cautioned to avoid early pollicizations.

Preferred Management

Incisions

Before inflation of a pneumatic tourniquet, the incisions are marked.^{87,90} A racquet-shaped incision is made at the base of the index finger just proximal to the digitopalmar flexion crease, with a radial extension that continues into the palm toward the new thenar flexion crease (Fig. 43-25, *A* through *C*). The palmar incision ends at the base of the index metacarpal. The rotation-recession movement of the index digit then invites a Y-V advancement of tissue from the radial border of the hand into the radial, mid-dorsal or ulnar surface of the transferred index ray. The exact placement of this incision depends on the tissue available and is not made before the index has been moved. Once the index digit has been moved and the metacarpal head fixed into position, a backcut incision is made on the dorsal surface of the index proximal phalanx (now the thumb metacarpal). Dorsal and ulnar skin flap from this digit is then rotated into the new first web space to create a more aesthetic web, which extends to the MP joint of the new thumb (formerly the PIP joint of the index finger).

The basic plan of the incisions for pollicization in the presence of a type IIIB or type IV (pouce flottant) hypoplastic thumb is not greatly altered. It is best to plan incisions first as though no thumb remnant is present and then to see how one can incorporate extra tissue into the original design. The level of hypoplastic thumb placement along the index ray, as well as the amount of tissue available, varies tremendously. Often in the Holt-Oram syndrome (congenital heart disease and radial dysplasia) a hypoplastic thumb is joined to a normal index ray by a complete simple syndactyly. In these cases, the thumb is excised through a midaxial radial incision at the same time as pollicization, but this can be performed as a separate procedure.

Soft Tissue Dissection

After meticulous marking, limb elevation, and exsanguination, the incision is made around the base of the index finger and into the palm. The dorsal skin flap is raised in an areolar plane superficial to the dorsal veins, lymphatics, and sensory nerves (Fig. 43-25, *D*). Palmar skin is elevated superficial to the palmar fascia. If present, the skeleton of the hypoplastic thumb is filleted from its soft tissue envelope and present intrinsic muscles are individually isolated and dissected to their proximal origin. The palmar fascia is then incised parallel to the index extrinsic flexor tendons, and the A1 pulley is incised in its volar midline (Fig. 43-25, *E*). The superficial palmar arch is identified and the vessels to both sides of the index ray are identified. The presence of fat cells and pacinian corpuscles often make the identification of neurovascular structures easier. The common digital artery to the index-long web space is followed to its bifurcation, and the radial digital artery to the long finger is ligated (Fig. 41-25, *F*). The radial digital nerve to the long finger is identified and separated proximally from the common digital nerve by fascicular dissection (Fig. 43-25, *G*). Neural and vascular loops are common on either side of the index ray and when noted should be dissected under appropriate magnification. The transverse metacarpal ligament is next incised (Fig. 43-25, *H*). Dorsal veins and nerves are not individually isolated from their dorsal soft tissue pedicle. Commonly, the major venous drainage from the index finger may join a large vein over the long metacarpal before it courses proximally. Dissection must then extend over the adjacent long metacarpal (Fig. 43-25, *I*).

Fig. 43-25 Pollicization technique. **A-C**, The illustration and palmar view show the plan for the incisions. The most important marking is the location of the future thenar flexion crease within the palm. The palmar base of the index finger will be the midportion of this flexion crease. The dorsal marking is made and the visible dorsal draining veins are marked by arrows. **D**, The palmar flaps are elevated above the palmar aponeurosis. **E**, A full release of the first annular pulley (palmar to the scissor tips) is completed. **F**, A neural loop around the common vessels to the web space must be carefully teased apart back to the level of the palmar arch. **G**, The common digital bundle to the index–long finger web space is isolated. The arborization to the radial side of the long finger (*red loop*) will be ligated. Note the neuroma in the dissected sensory nerve to the floating thumb, which was ligated in the newborn nursery. **H**, The transverse metacarpal ligament is exposed before its transection, which then provides increased mobility of the ray for the intrinsic muscle dissection. **I**, The dorsal venous system is easily exposed by scissor dissection between the two layers of dorsal fat/areolar tissue.

The interosseous muscles to the index finger are next identified. The palmar interosseous is consistently present on the ulnar side, whereas its dorsal interosseous partner on the radial side is absent in 50% of patients with thumb aplasia. Occasionally, the first dorsal interosseous muscle is found to have two muscle bellies. The distal skeletal and tendinous insertions need to be dissected carefully so that 1.0 to 2.0 cm of tendon is available for reattachment. These intrinsic muscles are then raised from distal to proximal toward the middle third of each muscle. Their metacarpal periosteal muscle origin remains intact and is saved and distal free periosteum is discarded, because it often becomes the site of ectopic bone formation.⁹⁰ The lumbrical of the index finger is not dissected (Fig. 43-25, *J* through *L*).

The extensor indicis proprius and extensor digitorum communis tendons to the index finger are then divided proximal to the extensor hood and reflected. These extensors require significant shortening before reattachment to the newly positioned index finger. Some shorten the extrinsic flexor tendons.⁹¹ This is best done in patients with stiff index fingers and those with associated radial dysplasia, because this will result in improved grip strength in those patients.⁹² This is done following osteotomy and repositioning

Osteotomy and Repositioning

Once the soft tissue dissection has been completed, the index metacarpal is exposed dorsally, and subperiosteal dissection is completed from the metacarpal base to the epiphysis (Fig. 43-25, *K* and *L*). Intrinsic muscle attachments to the periosteum are left intact. A transverse osteotomy is made through the epiphysis, and the collateral ligaments and palmar plate to the MP joint are left intact. With deep retraction, the metacarpal base is cut obliquely to serve as a pillar to support the index metacarpal head, which will be positioned anterior to it (Fig. 43-25, *M*). The metacarpal head, as part of an ovoid joint, becomes the trapezium as a substitute for the toroidal or universal saddle joint.

The shaft of the second metacarpal is removed and the index digit is both recessed and rotated into the thumb position. The metacarpal head is hyperextended and fixed volar to the base of the index metacarpal so that an appropriate metacarpal arch is created to simulate that of the normal thumb.^{90,93} This maneuver will orient the new thumb volar to the plane of the remaining digits. Intraosseous sutures through the metacarpal head and the dorsal strut of the index metacarpal are preferred to C-wires for fixation. Excellent retraction and meticulous attention to detail are required during this step, which often occurs 90 to 100 minutes after tourniquet inflation. The recessed index finger should lie in approximately 40 degrees of abduction and 120 degrees of pronation. Since the metacarpal head (now the thumb trapezium) is hyperextended, additional extension of the new thumb metacarpal is avoided. This maneuver is one of the most difficult during a pollicization procedure and requires careful retraction and assistance. The tourniquet is released for a 30- to 45-minute respite.

Intrinsic Rebalancing

Following recession and rotation of the index finger, the site of the backcut on the dorsum of the index finger is determined. This incision allows transposition of the ulnar skin to create a more aesthetic first web and a Y-V advancement of excess dorsal and radial skin from the palm (Fig. 41-25, *N* and *O*). It also provides wide exposure of the extensor mechanism for both intrinsic and extrinsic extensors reattachment. First the extrinsic extensors are shortened by approximately the same amount of metacarpal resection. The extensor digitorum is reattached to the base of the index proximal phalanx (now the thumb metacarpal) to simulate the abductor pollicis longus. Fixation on the ulnar side of the new metacarpal will help pronate the new thumb metacarpal. The extensor indicis proprius is interwoven into the extensor hood to act as the extensor pollicis longus. Next, the palmar interosseous (first PI) muscle is attached to the base of the index middle

phalanx (now the thumb proximal phalanx) to act as the thumb adductor pollicis. This muscle is often small and does not approach the new thumb with optimal mechanical advantage.

Occasionally, an excellent first PI and adductor pollicis are present with type IIIB thumbs. The first dorsal interosseous (first DI) (radial indicis, abductor indicis) muscle of the index finger becomes the new abductor pollicis brevis. If two muscle bellies are present, the deeper of the two is sutured to the radial base of the middle phalanx (now thumb proximal phalanx), and the other is then interwoven into the extensor mechanism distally at the level of the index PIP joint (now the thumb IP joint). Tension should be adjusted so that the thumb MP and IP joints are extended with the metacarpal in an abducted and pronated position. If the extrinsic flexors are not shortened, over time these will take up and provide more flexor tone. If they are shortened, the FDP is shortened by the same length as the metacarpal resection and done in zone III. The FDS tendon in this situation has been used as an immediate opponensplasty.⁹¹

Fig. 43-25, cont'd **J**, The first dorsal interosseous (abductor indicis) muscle has been detached from its distal bone and extensor insertions. Two distinct muscles are often found. **K** and **L**, The muscles are attached to their periosteal origin, which has been elevated off the metacarpal. The distal osteotomy is through the epiphysis and the proximal cut leaves the dorsal cortex of the metacarpal base. **M**, The metacarpal head becomes the new thumb trapezium and is placed in a hyperextended position in front of the metacarpal base (*inset*). Interosseous suture fixation is preferred to C-wires, which can cause problems in young children. **N**, With the thumb in its new position, the available skin is then draped over the dorsal surface before the cut-back incision is made. This maneuver makes maximal use of all available tissue. **O**, The extrinsic tendons have been shortened and reattached, and the intrinsic muscles have been attached distally, either to bone or the extensor mechanism via the lateral bands.

Continued

Fig. 43-25, cont'd **P**, The normal-appearing first web space is a gentle curve between the MP joint of the thumb and that of the long finger. Shaded area represents the area covered by the additional flaps rotated to create this web. **Q**, After closure, a broad web allowing maximal abduction should be present. **R**, The same hand is seen 21 years later.

Filletting the hypoplastic thumb remnant with removal of the bone, skin, and nail complex can subsequently be used for soft tissue augmentation of the new thenar region to assist in aesthetic improvement of the outcome.⁹⁴

Skin Closure

An eversion skin closure using both 5-0 and 6-0 catgut sutures starts at the base of the palmar incision. This closure helps to stabilize the position of the new thumb. The dorsal skin from the index has been advanced toward the long ray, so that an aesthetic thumb web extends from the MP joint of the new thumb and the MP joint of the long finger. Failure to do this will create an unnecessarily deep web space and give the appearance of a finger placed in the thumb position (Fig. 43-25, *P*). The flap advanced into the dorsum of the new thumb often contains an excess of subcutaneous fat. Debulking can be done, but only with great care to avoid injury to the venous drainage of the new thumb. No drains are required. After closure, a broad web allowing maximal abduction should be present (Fig. 43-25, *Q*). The patient is seen 21 years later (Fig. 43-25, *R*).

Dressing

Single-layer gauze impregnated with petrolatum is placed over the incisions and covered by a 2.0 to 3.0 cm thick layer of moistened cotton, which is molded to conform to the hand and new thumb. A bulky hand dressing is then applied, followed by application of a long arm cast well proximal to the elbow, which is flexed at 90 degrees. The thumb tip is left exposed to observe the circulation postoperatively, and the limb is elevated. The cast is removed 4 weeks postoperatively, and a thermoplastic thumb spica splint is fashioned with the thumb in abduction; this is to be worn at night for 2 months. During the day, unrestricted play is allowed. Many months may pass before active integration of the new thumb into hand function occurs. Buddy taping of the long and ring fingers is encouraged for children who persist with scissoring instead of thumb-long finger pinch or grasp.

Follow-up

These children require yearly follow-up to assess function and observe growth. As the first dorsal interosseous may be hypoplastic or absent in these children, secondary procedures are often required to achieve adequate palmar abduction. Transfer of the abductor digiti quinti is most frequently chosen. Other procedures that are occasionally required include extensor tendon shortening, tenolysis, scar revisions, debulking of dorsal fat, and dog-ear resection.

It is important to inform the parents that the pollicized index finger is not a thumb, but simulates a thumb. It will always be deficient in width, pulp, nail width, and joint motion. Manske and colleagues^{75,95} reviewed the function of pollicizations and found that the total active range of motion and grip strength was 50% and 21% of normal, respectively. Ninety-two percent of patients used the new thumb when manipulating large objects, whereas 77% did for small objects. Even though most patients used the thumb for performing tasks, it took them an average of 22% longer to do so. These results were adversely affected if the patient had an associated upper limb difference, such as radial dysplasia, a five-finger hand, or the mirror hand anomaly.

The most predictive preoperative variable is the condition of the index digit. Children with normal active and passive range of motion who have a normal component of intrinsic muscles and a normal distal radius and carpus will achieve much better results from a properly performed pollicization.

Treatment of a Stiff or Inadequate Index Finger

There are a number of clinical situations in which a less than adequate index digit is available for transfer into the thumb position. These include:

- Holt-Oram syndrome with a syndactylized index ray (Fig. 43-26)
- Index finger joined to the long finger with a complete simple syndactyly (that is, typical cleft hand, index-long finger syndactyly with absent or hypoplastic thumb)
- Stiff index finger associated with a complete or partial absence of the radius (Figs. 43-27 and 43-28; see Fig. 43-26)
- Stiff index ray with a fixed proximal interphalangeal joint flexion contracture, with or without a complete or partial absence of the radius (see Fig. 43-27)
- Mirror hand (ulnar dimelia), or the five-fingered hand

The clinical deficiencies of the index ray are obvious on physical examination; the major question is whether anything can be accomplished surgically to improve either the clinical function or appearance of the hand. The absence of flexion creases indicates deficient joint structures plus or minus inadequate extrinsic flexor or extensor myotendinous units. The presence of a complete or incomplete syndactyly means that there has been very little motion in utero. At surgery fibrous bands are present between the phalanges. Flexion contractures (camptodactyly) may be present in the index finger or all digits. These clinical situations do not present frequently but occur more often than one may anticipate. In our own combined experience, with more than 400 pollicizations performed over the past 29 years, one of these clinical scenarios is present at least 15% of the time.⁹⁰ There are no standard guidelines for treatment in the literature, and surgical recommendations are dependent on a given surgeon's experience. Most recommendations have been overwhelmingly conservative.*

Options for reconstruction include the following:

- Doing nothing
- Rotation-recession osteotomy of the index ray
- Formal pollicization of the index ray
- Pollicization of the fifth finger

*References 33, 75, 88, 90, 93, 95-106.

Fig. 43-26 Stiff index digit and radial dysplasia. **A**, This 5-year-old boy, who was born with an absent thumb and partial absence of the radius, underwent a centralization at 8 months of age and release of an index PIP camptodactyly at 1 year of age. **B** and **C**, Six months later, a rotational-recession osteotomy of the stiff index ray was performed, and **D**, the growth of the metacarpal head arrested 5 years later. **E**, Although this thumb has limited motion and slight excess in length, a very functional pinch has been maintained. The appearance is good. A strong index–first dorsal interosseous muscle, now the thumb abductor pollicis brevis, has stabilized the palmar abduction. The radiograph demonstrates the characteristic persistent radial deviation despite a good centralization with broadening of the distal ulna, which now looks more like a radius than an ulna.

Fig. 43-27 Rotation-recession osteotomy versus pollicization. **A**, This proud 7-year-old flexes his pectoralis major muscle transfer for elbow flexion. The hand and carpus had been centralized earlier, and his hand function was notable for good flexion and extension of the ring and fifth digits and, to a lesser extent, the long finger. The immobile index finger was scissored beneath the long finger with a 90-degree fixed flexion contracture of the PIP joint. **B**, This radiograph shows the characteristic widening of the distal ulna, which now looks like a radius several years after centralization. The index ray has good skeletal parts in a nonfunctional position. **C**, Following partial excision and arthrodesis in extension, the index finger was used as a post for the long finger. **D**, The incision for a rotation-recession osteotomy at the metacarpal level used the Y-V principle. **E**, The digit was shortened 8.0 mm and abducted to create a wider first web space.

Fig. 43-28 Thumb position after pollicization. **A**, This child, seen 6 years after bilateral pollicizations, had a normal radius and index digit on the left and a short radius with a stiff index ray on the right hand. **B**, The left thumb, with excellent motor function, can be placed in more palmar abduction and extension. **C**, The stiffer right thumb is placed closer to the long finger so that tip-to-tip prehension is possible. The right thumb would be a functional liability if placed in the same position as the more mobile left thumb. Before pollicization on the right side, camptodactyly releases were performed at the PIP joint level of all four digits.

The possible combination of deformities with congenital hand differences is infinite, and there are many instances in which it is possible to pollicize an index digit after a number of previous procedures involving this ray have been completed. Most examples involve either a syndactylized index finger within a mitten hand or a typical cleft hand in which the index and long fingers are joined within a simple syndactyly. In either case, the syndactyly is released before formal repositioning of the index digit.

Determining what to do and how to do it can be made much easier by analysis of larger series of pollicizations. The quality of the result depends predominantly on the preoperative condition of the index ray. Optimal results are predictable following a well-executed operation on an index finger with normal active and passive range of motion and a full complement of median- and ulnar-innervated thenar intrinsic muscles. The radius is usually normal in these children. In the five conditions listed on p. 1329, the index and long digits have diminished motion, and the ring and small (fifth) digits are mobile and functional. In these hands the position of the pollicized index finger is crucial so that it will be well positioned for a pinch to the long finger and a grasp to the fifth finger. In most cases the new thumb will have diminished extrinsic motion, particularly in extension, because the muscles originating on the radial side of the forearm are either abnormal or absent. It is most important that this thumb be positioned for good opposition to the fifth finger, a posture that places it in less abduction than normal (see Fig. 43-28). If placed in too much palmar abduction and extension, this immobile post will be caught on objects or within pockets.

One alternative rarely chosen in these patients is the rotation-recession osteotomy in lieu of a formal pollicization. We have preferred this procedure in teenagers and adults with a stiff, flexed index finger (see Fig. 43-27), those with scarring from previous procedures, mirror hands, a five-fingered hand, and a very stiff index ray associated with a radial club hand. The principles of treatment are the same, but the ray is not shortened to the full extent of a formal pollicization. What intrinsic muscles are present are reattached and the extrinsic flexors and extensor tendons are shortened as appropriate. The position of the new thumb must be very carefully chosen for optimal pinch. Many of radial club hand patients are born with a camptodactyly involving all proximal interphalangeal joints, which become progressively more severe in the most radial index

and long digits (see Figs. 43-27 and 43-28). In these contracted digits we also perform full releases with Z-plasties or full-thickness skin grafts if needed and then consider a rotation-recession osteotomy instead of a classic pollicization.

When assessing the outcomes of pollicization, one needs to consider whether there is an isolated thumb anomaly or if there is an associated forearm condition. In studies that have looked at the outcomes of pollicization, those children with an isolated thumb anomaly performed better after pollicization compared with those with concomitant radial dysplasia. The total active range of motion (TAM) of pollicized index fingers in children with isolated thumb anomalies is reduced (89 to 146 degrees) when compared with age-matched children with normal thumbs (185 degrees). If there is associated radial dysplasia, there is even a further reduction in the TAM of those pollicized digits.^{95,107-109} Strength, as measured by pinch and grip strengths, is also reported to be significantly less than age-matched normals in children following pollicization. When comparing strength in isolated thumb anomalies these fare better than those with associated radial dysplasia.^{95,107-109}

Refinements in Index Pollicization

Most surgical procedures represent a dynamic process and are amenable to alteration and refinement and pollicization is no exception. Although the very specialized elements of the thumb such as the basal saddle joint, the asymmetric condylar surface of the proximal phalanx and the contoured pulp surface and the broad distal phalanx are impossible to replicate, a close replica

Fig. 43-29 The highly specialized pulp surface of the thumb with the great toe and index finger is compared. The contoured thumb with its slightly upgraded contact surface cannot be concisely replicated by these close substitutes.

is possible (Fig. 43-29). Working over a span of almost 80 years, the senior author (J.U.) and his mentor (J.W. Littler) have studied their craft critically.^{110,111}

Incisions

With the basic rotation and recession of the index ray into the thumb position, all incision designs involve a Y-V manipulation of skin, and this operation is no exception. Initially, Littler placed the V at the radial base of the index ray and made a small cut-back incision for the inset. The result was a new thumb in good position with imperfect contour within the first web space¹¹² (Fig. 43-30). The contour between the new thumb and long digit was not a gentle one, which flowed from the MP joint of the new thumb (previously the index PIP joint) and the MP joint of the long digit.

Two refinements have subsequently been made. The first places the palmar incision in what would be a normal thenar flexion crease (see Fig. 43-25) in a more central position and the second has been to delay the cut-back incision until the index has been placed into its new position. At that time the skin over the dorsal surface can be draped over the new thumb and a more precise cut can be made on the dorsal surface. This is usually over the mid-dorsal surface up to the level of the MP joint (previously the index PIP) and allows for easier rotation of the tissue on the ulnar

Fig. 43-30 Original incision design. Littler's original design placed a cut-back incision on the radial base of the index finger, which allowed the inset of a V-shaped flap of thenar skin. This resulted in a V-shaped cleft between the thumb and long digit and a thenar flexion crease on the radial side of the hand. The refinements discussed have created a more natural-appearing web, which extends from the MP joint of the new thumb to the MP joint of the long digit.

Fig. 43-31 Cut-back incision. Once the rotation-recession of the index ray has been completed, the dorsal tissue can be draped over the thumb in its new position. Its apex is marked and an incision made over the proximal phalanx of the index digit, which is now the new thumb metacarpal. In this case, the most appropriate incision was in the middle. However, it may also fall along the radial or ulnar surface dependent upon the soft tissue available. The skin on the ulnar surface is then available to be advanced into the more contoured first web space.

side of the index finger into the new web space (Fig. 43-31). The delay in making this strategic incision enables the surgeon to make maximal use of all soft tissue available.

Carpometacarpal Joint

The normal thumb carpometacarpal (CMC) joint represents an absolute marvel of engineering: it permits motion in four directions (abduction, adduction, flexion, and extension), plus limited rotation in pronation and supination. In a hyperextended position, the index MP joint permits only flexion and extension. The original pollicization design simply shortened the metacarpal and placed the metacarpal head at its base. With the head in an extended position, the new thumb would not hyperextend in its new position. The refinement has been to make certain the growth plate has been obliterated. Growth of the metacarpal head is not desired, since the transferred metacarpal head is close to the size of a normal trapezium. With the joint in a hyperextended position, the index metacarpal head (now the new thumb trapezium) is placed anterior to the base of the index metacarpal. The previously described osteotomy is made at the base and the metacarpal head sutured into its new position. The metacarpal head is sutured into its new position and the use of pins is avoided (Fig. 43-32). (C-wires in children are often the source of problems.)

Extrinsic Tendons

The refinement in technique has been to use the index extensor digitorum communis as a new abductor pollicis longus, which is inserted onto the ulnar base of the new thumb metacarpal (previously the index proximal phalanx). In this new position, it will effectively extend the new thumb metacarpal and pronate as much as the new CMC joint will allow¹¹² (Fig. 43-33).

Intrinsic Muscle Rebalancing

The rebalancing of the intrinsic muscles is critical for the stabilization of the new ray in the thumb position. There is great variation in the size and quality of these muscles and their dissection and reinsertion requires experience. We prefer to insert the first dorsal interosseous (first DI) (also called *the abductor indicis*) muscle directly into bone, because this single insertion gives it a direct

Fig. 43-32 CMC joint. **A**, The distal osteotomy of the index metacarpal is made through the growth plate at the level of the collateral ligaments. **B**, All epiphyseal cartilage is removed down to the level of bleeding cancellous bone. To avoid hyperextension of the new thumb, this joint is then placed in hyperextension in its new position. **C**, An oblique osteotomy is made at the base of the index metacarpal and the palmar cortical surface is removed. The recessed (shortened) and rotated metacarpal head is then inset into this new position and secured with an interosseous suture.

Fig. 43-33 Extrinsic extensor tendons. The two extrinsic tendons to the index digit, which must be rebalanced. **A**, A Littler drawing shows the tendons from the dorsal surface. In normal positions, the extensor indicis proprius is ulnar to the extensor digitorum communis. The abductor indicis is the first dorsal interosseous muscle. The new thumb projection is indicated. **B**, In the new thumb the extensor indicis proprius, an independent muscle tendon unit, is shortened to become the new extensor pollicis longus. The refinement is that instead of being sacrificed, the extensor digitorum communis is shortened and sutured to the ulnar base of the new thumb to become the abductor pollicis longus. With its pull exerted on the ulnar surface of the new thumb, additional pronation may be achieved. (*Detach ai*, Detach abductor indicis or first dorsal interosseous muscle; *EDC*, extensor digitorum communis to index digit; *EIP*, extensor indicis proprius; *Epiphysis*, growth plate in metacarpal head; *I*, thumb ray; *II*, index ray; *III*, long metacarpal; *Volar i*, volar interosseous muscle.)

Fig. 43-34 Intrinsic rebalancing. **A**, In contrast to a normal thumb, which has three layers of intrinsic muscles, the index ray contains only two muscles that require reinsertion: the first dorsal interosseous (first DI) becomes the abductor pollicis brevis and the palmar interosseous, which becomes the adductor pollicis of the new thumb. **B**, The lateral bands have been prepared for intrinsic reinsertion on their side of the extensor mechanism. **C**, The volar interosseous has been attached to the ulnar lateral band of the extensor mechanism and a similar insertion for the larger abductor indicis. When two heads are present, dual skeletal and extensor insertions may be performed. (*Detach ai*, Detach abductor indicis or first dorsal interosseous muscle; *EDC*, extensor digitorum communis to index digit; *EIP*, extensor indicis proprius; *Epiphysis*, growth plate in metacarpal head; *I*, thumb ray; *II*, index ray; *III*, long metacarpal; *Volar i*, volar interosseous muscle.)

pull with all power concentrated at one point. In those with a normal index ray, this muscle often has two portions and the larger is preferably attached to bone and the smaller interwoven into the extensor mechanism. The older interweave of the lateral bands into the distal portion of these muscles is secure and often more stable than direct tendon-to-tendon sutures (Fig. 43-34).

In individuals with a stiff index ray, often associated with a complete or partial absence of the radius, the first DI is small and often insufficient to hold the new thumb in palmar abduction. Secondary tendon and/or muscle transfer is needed to provide this function. The palmar interosseous muscle is always much smaller—and equally as variable as the first DI. After the rotation and recession of the index ray, this muscle becomes the adductor pollicis of the new thumb. It may be inserted into either the lateral band or directly onto the ulnar side of the proximal phalanx or MP joint. The major problems with this often diminutive muscle is that it may cause too much adduction of the new ray. For this reason, we may provide additional length with a lateral band interweave or just discard the reinsertion if the muscle is small and has minimal excursion.

The final refinement here is to adjust the proximal origin of the first DI. When space is being cleared at the metacarpal base for the reception of the metacarpal head, the muscle origin and its periosteal attachments are often elevated. This maneuver provides an opportunity to adjust the tension of this muscle at its proximal origin; a move that occurs before the final skin closure.

Suturing

Comparison of preoperative and postoperative plaster molds of these patients up to 10 to 20 years later often highlights the dramatic appearance of a “railroad track” incision made with 5-0 sutures during the first few years of life. For this reason, we prefer to close these wounds in layers using 5-0 or 6-0 absorbable sutures for the deep layers and approximation of the epidermal surface with an intracuticular technique. Stitch marks are always more conspicuous in dorsal hair-bearing skin than in palmar glabrous skin.

Adipofascial Flap

In children with type IIIB or type IV thumb hypoplasia, the extra skin, fat, and/or pulp tissue does not necessarily need to be discarded. Much of this tissue can be saved as a vascular island and placed subcutaneously at the radial base of the new thumb to produce a simile of a thenar eminence.⁹³ This augmentation is not with a functional muscle but does create a significant improvement in appearance (Fig. 43-35).

Metacarpal Arch

Anterior placement of the metacarpal head during pollicization helps to simulate the normal concavity of the proximal palm and the transverse metacarpal arch (Fig. 43-36). It also allows easier fixation of the metacarpal head in permanent extension.

Fig. 43-35 Adipofascial flap. **A**, Following a fillet of skin and skeletal components, the remaining soft tissue of this type IIIB thumb has been preserved on **B**, a vascular pedicle and **C**, placed at the base of the new thumb. This additional bulk in a strategic area improves appearance.

Fig. 43-36 Carpal arch. Anterior repositioning of the index metacarpal head. **A**, Coronal view; **B**, axial view. This helps to simulate the normal concavity of the proximal palm. **C**, The trapezium is outlined in dotted form in a normal carpal arch (axial view). (*I*, Thumb metacarpal; *II*, index metacarpal; *III*, long metacarpal.)

Other Revisions

Both function and appearance can be improved with secondary revision. The contour and breadth of the pulp can be augmented with composite glabrous pulp grafts harvested from the lateral side of the great toe (if present). Grafts with a width of up to 12 to 13 mm can be harvested with primary donor site closure in older children.

Lack of palmar abduction (opposition) can be improved with tendon or muscle transfers. Our preference for restoration of palmar abduction (opposition) has been the flexor digitorum superficialis passed around the flexor carpi ulnaris. The abductor digiti quinti muscle (Huber) transfer has also been used as our second choice. The major modification we have made with this transfer has been to include glabrous skin as a myocutaneous flap. The incision is the same along the ulnar border of the hand, and passage of the muscle through a subcutaneous tunnel is avoided, because a straight incision is made along the radial side of the thumb for direct inset. The complex relationship between the abductor and flexor pollicis muscles must be respected, since it is often wise to include both in the transfer. The opponens pollicis muscle can usually be left undisturbed at the base of the wound. This transfer has been used more frequently for type IIIA hypoplasias (Figs. 43-37 and 43-38).

Fig. 43-37 Abductor digiti quinti muscle transfer (ADQM; Huber transfer). **A**, ADQM transfer for palmar abduction as muscle alone is isolated on its vascular origin within Guyon's canal. Additional length is achieved by split of the flexor carpi ulnaris. The skeletal (1) and extensor (2) insertions are anchored into the bone (2) and extensor (1) of the thumb. Transfer is likened to turning the page of a book. **B**, A subcutaneous path was initially preferred before the introduction of myocutaneous flaps. (*a* [and 1], *b* [and 2], Skeletal and tendinous insertions of the abductor digiti quinti muscle; *abd Dig V*, abductor digiti quinti muscle; *FCU*, flexor carpi ulnaris; *Flex Dig V*, flexor digiti quinti muscle; *P*, pisiform bone.)

Fig. 43-38 Abductor digiti quinti myocutaneous flap/transfer. **A**, Appearance of a hypoplastic hand with type IIIA thumb hypoplasia with no functioning thenar intrinsic muscles. **B**, The abductor digiti quinti and flexor digiti quinti have been isolated together with a skin island and, still attached to the pisiform, the opponens digiti quinti remains intact. **C**, The resultant pull is directly across the palm. The skin island serves to further augment the base of the thumb. **D**, The muscle functions very well, and the color match and contour of the glabrous skin is ideal.

Central Deficiencies of the Hand With Thumb Abnormalities

There are two congenital hand differences that include central deficiencies within the hand and that were historically designated as the typical and atypical cleft hand. The latter is now called *symbrachydactyly*. Both conditions may have significant thumb malformation and are included as types of thumb hypoplasia.

TYPE VI CLEFT HAND: ECTRODACTYLY

Anatomy

Cleft hand is characterized by hypoplasia or aplasia of the central rays of the hand, thus forming a V-shaped or funnel-shaped cleft. All degrees of simple syndactyly of the first web are seen, resulting in moderate to severe deficiencies of the first web space. All degrees of hypoplasia extending to aplasia of the central two rays may exist. The ulnar two digits in the ring and fifth positions are commonly webbed with simple syndactylies. The thumb in the cleft hand anomaly is

Fig. 43-39 Thumb hypoplasia and the cleft hand. **A**, Three layers of median-innervated intrinsic muscles are present in most typical cleft hands. Commonly, the index ray is joined to the thumb by a simple syndactyly. All degrees of absence of the long rays may be present. The first dorsal interosseous is present and tight, and the degree of adductor pollicis hypoplasia is proportional to the amount of the third metacarpal present. A very small adductor pollicis is illustrated. **B**, A sampling of molds shows the wide variation in the size and depth of the central clefting. The thumbs are smaller than normal, and the longer thumbs with flexion contractures are triphalangeal.

Fig. 43-40 Cleft hand. **A**, Clinical appearance and **B**, radiographs of both hands in this 4-year-old child show unstable thumbs at the MP joint level. Despite the wide central cleft and the absence of index and long digits, the child's function was remarkably good. Subsequent surgery consisted of ulnar collateral ligament reconstruction of both thumbs and a camptodactyly release on the right ring digit.

usually slightly smaller in size, with all components of the osteoarticular skeleton being present (Figs. 43-39 and 43-40). A Blauth type II thumb classification⁴¹ would be appropriate for a strict constructionist. The carpus and forearm bones are normal. The major deficiency of the thumb in this form of hypoplasia is that the ulnar-innervated intrinsic muscles are severely hypoplastic or absent. The median-innervated thenar intrinsic muscles are normal. In particular, the ulnar-innervated adductor pollicis is usually severely hypoplastic or absent, and the first dorsal interosseous muscle is moderately hypoplastic and contracted. Collateral ligament instability at the MP joint is common in most forms (see Fig. 43-40). The presence or absence of the third metacarpal is often an excellent indicator of the status of the adductor pollicis muscle. The extrinsic flexor and extensor myotendinous units to the thumb tend to be unaffected. A very important consideration in the correction of any cleft hand is the status of the long metacarpal and the adductor pollicis muscle (Fig. 43-41).

In another variation of cleft hand, thumb duplications at all levels may be observed. The more distal type I and II duplications are often associated with an absence of index phalanges with an intact metacarpal. Transversely oriented tubular bones at the distal metacarpal level are often seen with complete absence of the index (and long) digits. Superdigits are often seen in this variation.

Fig. 43-41 The importance of the adductor pollicis muscle. **A**, A strong adductor muscle should be saved, because a weak pinch is a predominant feature of the cleft hand. Three common variations seen in cleft hands are seen on the left as a hypoplastic metacarpal with a strong muscle (*top*), a transverse phalanx with the adductor inserting into the next ulnar bone (*middle*), and a very hypoplastic metacarpal with a very deficient muscle (*bottom*). **B**, Two alternatives for treatment in these hands include the transposition of the distal index metacarpal on top of the existing long metacarpal (*top*) or a subperiosteal removal of a hypoplastic long metacarpal and transposition of the index into the periosteal sleeve (*bottom*). The transverse phalanges seen in the left center are excised completely. (1, Thumb metacarpal; 2, index metacarpal; 3, long metacarpal; 4, ring metacarpal.)

With more proximal type III, IV, and V duplications, the central (third) ray is often severely hypoplastic or absent. Triphalangeal duplicates may also be encountered with the proximal types.

Management

In treating a patient with a cleft hand anomaly, the following principles should be followed:

- Release of the first web syndactyly and contracture
- Ulnar transposition of the index finger to close the central cleft
- Construction of an intermetacarpal ligament between the second and fourth metacarpals
- Preservation of the adductor pollicis, if present, with its origin from the periosteum of the third metacarpal
- Transposition or rotation of the skin from the central cleft into the first web to cover the newly created web space (Fig. 43-42)
- Release of any syndactyly involving the two ulnar digits
- Treatment of the thumb duplication in a standard fashion (see Chapter 46)

Fig. 43-42 Cleft hand correction incisions. **A**, Despite the degree of thumb hypoplasia, the approach to cleft hand remains consistent. Incision outlines on dorsal and palmar surfaces of the hand show a commissure flap on the radial side of the ring digit and equal division of tissue within the depth of the central cleft. All glabrous tissue remains palmar, and nonglabrous (hair-bearing) tissue remains dorsal. The major difference between our incision and the Snow-Littler incision is that we do not depend on a dorsally based flap to line the first web space. **B**, After flap elevation, there is wide exposure of all important neurovascular structures, the adductor pollicis (AddP), first dorsal interosseous (first DI) muscles, and all skeletal structures. There is easy access to all anatomy down to the CMC joint level. (This incision is the equivalent in the hand of the coronal incision used by craniofacial surgeons.) Complete exposure of all important structures is afforded by a direct incision. **C**, After transposition of the index ray, both flaps are moved into the first web space. Z-plasties or other transposition flaps can be used to improve contour.

Options

Several procedures have been described to accomplish the previously listed principles for the management of this condition.^{82,113-116} Flaps of the cleft skin based on either the volar or dorsal surface have been used. Both of these designs suffer from the same anatomic problem in that the skin flap from the cleft is a random-pattern flap, and the viability of the distal portion of the flap can be suspect. More recently, Tajima⁸⁴ has described closure of the newly created first web with a dorsal sliding flap. This design certainly has less risk associated with the vascularity of the skin flap.

Our preferred method of thumb correction uses simple incisions, much like those designed for a pollicization. An incision is made on the ulnar side of the index ray, which is then transposed as a vascular island to the long position. The metacarpal is either disarticulated and transposed at the CMC joint level, or, when a suitable portion of the third metacarpal base is present, osteotomy of the second metacarpal and transposition of this and osteosynthesis is then performed on top of the third metacarpal remnant. Dorsal and palmar flaps are raised and sutured directly to the skin flaps created by incision of the ulnar side of the cleft (see Fig. 43-42). Simple or complex Z-plasties can then be performed on either side of the thumb index web space as deemed necessary for contour improvement.

A number of autosomal dominant cleft hand and foot syndromes exist (Fig. 43-43). Genetic counseling may be required for those patients with bilateral cleft hand-foot anomalies, which are associated with an autosomal dominant pattern. In these patients a transverse failure of formation of the thumb may be present at the metacarpal or phalangeal level. Vascularized toe-to-thumb transfer using the distal portion of the great toe (if present) is preferred for thumb reconstruction when no phalangeal segments are present. Distraction lengthening is another alternative for lengthening. Motion in these thumbs is poor, sensation is good, and function is very gratifying, because the deformities are always bilateral. Secondary procedures are commonly needed for correction of intrinsic joint laxity or deviation.

Fig. 43-43 The thumb in a cleft hand. **A** and **B**, The left hand and radiograph of a young child with an unusual cleft hand shows a triphalangeal thumb, a duplication at the metacarpal level, a short index ray with no distal phalanges, and a transverse bone connecting the long and ring metacarpals at the MP joint level. **C**, The proposed reconstruction. In a first stage, the index ray (c) was transposed on top of the long metacarpal (f). Only the ulnar portion of the transverse bone (b) was saved because it articulated with the ring proximal phalanx.

Continued

Fig. 43-43, cont'd D-E, At the second stage, the thumb duplication (*a, b*) was transferred on top of the index ray to make a longer and more complete digit. Nerves and tendons were all joined. G-I, The patient developed a very functional pinch between the long (and untouched) triphalangeal thumb and the index finger. Her hand and the radiograph are seen at skeletal maturity. The patient has become a very confident young woman and, in fact, has won regional New England piano competitions.

TYPE VII THUMB HYPOPLASIA: SYMBRACHYDACTYLY (ATYPICAL CLEFT HAND)

Anatomy

This form of longitudinal deficiency is always unilateral with varying degrees of hypoplasia of the central three rays of the hand. Nubbins with minute nail complexes may be present on the distal border of the palm representing the index, long, and ring fingers, but commonly there is complete absence of the central three digits, with varying degrees of hypoplasia of the central three metacarpals. All degrees of variation exist; no two hands are identical. The thumb in this condition is invariably smaller, with severe hypoplasia or aplasia of the adductor pollicis, but a metacarpal with two hypoplastic phalanges is usually present. Occasionally, a metacarpal and distal phalanx is present with a flail thumb at the MP joint level (Fig. 43-44). With an intact third metacarpal, a functional adductor pollicis muscle is often present. The median-innervated thenar intrinsic muscles are intact and usually small or normal. The thumb CMC joint is well segmented and mobile. The IP joint of the thumb may exhibit decreased passive and active motion as a result of weak extrinsic flexor and extensors. On exploration, the FPL tendon is often traced back to a hypoplastic or absent muscle belly in the distal forearm. In a severely hypoplastic thumb, there

Fig. 43-44 Thumb hypoplasia and symbrachydactyly. **A**, The border thumb and fifth rays are the most complete in the hand. Thenar and hypothenar muscles are present and often small. Central digits are represented by hypoplastic nubbins. There are all degrees of metacarpal hypoplasia within the central three rays of the hand. Extrinsic flexors and extensors are present but abnormal. **B**, A very wide range of variation is present in these hands.

is significant limitation of MP motion, an absent IP flexion crease, and only a rudimentary FPL tendon. The fifth ray is usually the best in the hand, with intact intrinsic and extrinsic myotendinous units. Frequently this digit has a radial clinodactyly and completely unstable MP joint. The entire hand is hypoplastic. Radius and ulna are present and of equal length but may be small in comparison to the opposite limb.

Management

Observation of these children at play will provide insight into the need for any surgical reconstruction. Children with this congenital upper limb difference tend to be among the most functional of any, because virtually all can oppose and some can touch the thumb to the small finger. They all have the components of a basic hand: a mobile radial ray, a cleft (which acts as a web

Fig. 43-45 Thumb in symbrachydactyly. **A** and **B**, The left hand of this child with Moebius syndrome was reconstructed with a second toe transfer at 18 months of age and is seen on the right when the patient was 5 years of age, during the distraction lengthening of the fifth metacarpal. The distraction was done in two stages: (1) osteotomy and application of distractor and (2) bone grafting. **C** and **D**, Ten years later, the second toe transfer continues to grow in comparison to the ulnar metacarpal post.

Fig. 43-46 Thumb in symbrachydactyly. **A** and **B**, The left hand and radiograph of a patient with generous soft tissue nubbins, which represent the thumb and digits. **C** and **D**, He was an ideal candidate for nonvascularized toe phalangeal transfer to the thumb and index rays. The first web space was also deepened and widened with local flaps. Despite the limited mobility, this reconstruction is very functional as a helper hand.

space) and an additional ray or post on the opposite side of the hand for pinching and grasping functions (Fig. 43-45). Consequently, most of these children do not require any operative intervention, and to provide it may be quite meddlesome.

Excision of the nonfunctional nubbins will improve the shape of the cleft and provide a deeper web space for grip. Some patients with this anomaly have a thumb deficient in length and unable to oppose to the highly mobile ulnar border digit. In these patients distraction lengthening can improve both function and appearance. These patients may also lack pulp-to-pulp pinch as a result of poor pronation of the thumb during pinch maneuvers. Rotational osteotomies at the metacarpal level will resolve this problem by placing the digits in a more favorable position. A severely hypoplastic thumb with an absent or diminutive proximal phalanx and a flail MP joint is best treated with a nonvascularized toe phalangeal transfer into the proximal phalangeal level.

Although motion is not restored, the thumb becomes a functional post. These transfers are more likely to grow if performed before the child is 1 year of age,^{117,118} although other studies have questioned the amount of actual long-term growth.¹¹⁹ Placement of a nonvascularized phalangeal transfer will provide bone stock for potential future distraction lengthening. Ablation of the small distal phalanx and second toe microvascular transfer is an option best performed between 2 and 4 years of age (Fig. 43-46).

The ulnar digit in symbrachydactyly will often have an unstable MP joint and radial clinodactyly as a result of its asymmetrical proximal phalanx. The flexor tendons are strong and the extensors present but unbalanced. Stabilization of the MP joint with chondrodesis, bone grafts, and transfer of nonvascularized toe phalanges have all been performed, with varying degrees of success. When positioned as a stable post, these fifth rays function quite well for hooking and balancing maneuvers.

TYPE VIII THUMB HYPOPLASIA: CONSTRICTION RING SYNDROME (AMNIOTIC BAND SEQUENCE)

Anatomy

Constriction ring syndrome (also called *amniotic band sequence* or *Streeter's dysplasia*) is a condition that can affect any one or all of the limbs and, uncommonly, the face. As defined by Patterson,¹²⁰ limb involvement can result in any of the following deformities^{82,120}:

- Simple constriction rings, which may be partial or circumferential
- Constriction rings with distal deformity, with or without concomitant lymphedema
- Acrosyndactyly (distal fusion, fenestrated syndactyly)
- Amputation

Hypoplasia of the thumb is seen in this condition when there is a deficiency in the length of the thumb, which may have a transverse amputation at any level (Fig. 43-47). Occasionally, the existing skeletal and soft tissue components of the first ray may be hypoplastic. The hallmark of the amniotic band sequence is that the anatomy proximal to the level of amputation or band is normal. Either superficial or deep constriction rings (annular bands) can be associated with hypoplasia or lymphedema of the distal segment of the digit with hypoplastic nail remnants and slender, truncated phalanges present. Acrosyndactyly usually involves the central three rays of the hand but can also involve the thumb and fifth finger in a large syndactylized complex. Amputation of the thumb in this condition is the major cause of partial aplasia of the thumb and, as previously mentioned, can occur at any position along its length. When considering the management of the level of amputation, it is best to do this at one of three levels: distal to the IP joint, the proximal phalanx, or the metacarpal (see Fig. 43-47). Motion of the IP joint is usually severely affected, even with amputations or deep constriction rings distal to it.⁸²

Management

The following principles apply to the management of these thumbs:

- Immediate treatment of emergency conditions such as vascular compromise and progressive lymphedema
- Early liberation of the thumb ray from an acrosyndactylous complex
- Release of adduction contractures within the first web space when present

After release of the first ray, the functional requirements of the patient must be accurately determined. Several options are available, and the management of each patient should be carefully individualized. In individuals with distal amputations at the phalangeal level, no operative intervention may be the best course of action.

Fig. 43-47 Type IX thumb hypoplasia: constriction ring syndrome (CRS). **A**, The thumb in such hands may have a shallow or deep constriction ring or a congenital amputation at any level along the skeletal ray. The phalanges at the level of loss are characteristically narrow and taper to the distal stump. **B**, The intrinsic muscles are all present up to the level of the amputation. The proximal anatomy in this condition is normal. **C**, The thumb is absent on the left and shows increasing length in these molds. No two hands are identical; there is great variation in the depth and location of constriction rings along the digits.

Options available for lengthening the deficient thumb ray in this condition include distraction lengthening, nonvascularized toe phalangeal transfer, and composite vascularized toe-to-thumb transfer or local partial ray transfer.

Distraction lengthening^{121,122} is best performed at the metacarpal level if satisfactory bone stock is present. The metacarpal can be easily but slowly lengthened up to 100% of its length as a two-stage procedure, which includes application of a distractor and an osteotomy, followed by bone grafting within the intercalated gap. Lengthening of deficient, terminal, and often-narrowed phalanges in this condition is not as predictable. The resulting digits are often stiff and thin. Distal nonunions and exposures are common complications. Second toe composite transfers are preferred to distraction at the phalangeal level (Fig. 43-48).

Transfer of nonvascularized toe phalanges^{117,118,123} is an excellent way to provide length and growth potential to an empty, redundant soft tissue envelope occasionally seen distal to the level of amputation in this condition. Extraperiosteal harvest of the third or fourth toe proximal pha-

Fig. 43-48 Constriction ring syndrome treated with distraction lengthening. **A**, Radiograph of a young girl with a congenital amputation at the thumb interphalangeal joint level with a tight first web space. Note the tapered appearance of the proximal phalanx. **B**, A distraction apparatus is pulling each end of the metacarpal away from the osteotomy site at the middle diaphyseal level. One clockwise turn of the screw equaled a 1.0 mm gain. **C**, The new bone regenerate (*callostasis*) advances toward the midportion of the gap created. The stretching injury to soft tissue is impressive. All vessels, nerves, and tendons are intact. **D**, The thumb metacarpal is now as long as the index. **E**, Five years later, both metacarpals are growing, but the index is now longer. **F**, The first web space was deepened to increase thumb mobility and increase its span. **G**, Although shorter than normal, this thumb has functioned very well on her dominant hand.

lanx and transfer will result in survival and growth of the phalanx in 90% of patients younger than 2 years of age (Fig. 43-49). Our own experience has not been as successful: only 70% of these phalanges transferred early in life have retained normal growth potential. Survival and growth will occur in patients older than 2 years of age, but at a less predictable rate. The second toe is spared so that the entire toe is available for vascularized composite transfer if required. Secondary distraction lengthening of the transferred phalanx can be performed if further length is required.

In patients with a congenital amputation through the proximal phalanx or metacarpal, composite microvascular transfer of a second toe has been our procedure of choice. The great toe can be transferred as either a complete or as a modified unit,¹²⁴ but this option has been reserved for uncorrected thumb deformities that present after childhood. Because of the normal anatomy proximal to the level of amputation or band and an intact CMC joint, an excellent functional and aesthetic result of the “toe” can be obtained. The presence of functional thenar intrinsics will also enhance the result (Figs. 43-50 and 43-51).

Fig. 43-49 Thumb with constriction ring syndrome treated with a toe phalanx. **A-D**, In this child with CRS acrosyndactyly, the fibrous connections holding all fingertips were released in the newborn nursery. Her thumb ends at the metaphysis of the proximal phalanx and the index finger at the middle phalanx. Nonvascularized toe phalanges from the third and fourth toes were transferred on top of the index finger and thumb. **E**, The periosteum is intact, and the collateral ligaments and volar plate are attached to the skeletal part at the amputation stump. Joint motion was preserved in this child. **F** and **G**, A four-flap Z-plasty deepened the first web space and improved her grasping ability. She is now 20 years of age and has had normal growth of the transferred phalanges. No further reconstruction has been performed.

Fig. 43-50 Thumb in constriction ring syndrome. **A**, This radiograph of a child with acrosyndactyly following release shows congenital amputations of the thumb at the IP joint level, the index and ring digits through the middle phalanx, and the long digit through the proximal phalanx. **B** and **C**, A radiograph and clinical appearance of the same hand 18 months later. **D** and **E**, The index phalanges were transferred on their vascular pedicle as a pollicization to lengthen the thumb, which already had a good complement of thenar intrinsic muscles. The constriction ring of the fifth digit was corrected. Skin grafts were needed on the ulnar side of the new thumb. **F**, When the patient was 3 years of age, a double second and third toe composite transfer was performed on top of the long and ring digits. A syndactyly release was performed 3 months later. **G** and **H**, At 6 years of age, this girl is a very confident first grader with a mobile thumb and a strong pinch.

Fig. 43-51 Thumb with constriction ring syndrome treated with microvascular toe transfer. **A-C**, This boy, born with acrosyndactyly, had thumb loss at the interphalangeal joint level, no first web space, and congenital amputations of the index and long digits at the phalangeal level. The connecting bands present at birth were released in the newborn nursery. His first surgery was a distally based radial forearm fasciocutaneous flap to the first web space and release of the camptodactyly of the ring finger. **D-F**, Thumb length was augmented with a modified great toe transfer. A methylmethacrylate mold of the opposite normal thumb was used to measure and contour the larger great toe at the time of operation. The incision markings are shown on the ipsilateral great toe, and the specimen is seen in transit to the recipient left thumb. **G** and **H**, Four years later. Thumb sensation is normal, and motion measures 30 degrees at the IP joint and 50 degrees at the MP joint. The contour has been excellent. No revisions have been performed.

In several children we have first lengthened a deficient metacarpal with an intact CMC joint to provide a good foundation for second toe transfer. The keys to this procedure are to proceed slowly, to minimize soft tissue dissection, and to avoid injury to growth centers. The major problem with any toe transfer is the availability of toes, which, like the fingers, may be hypoplastic or aplastic.

Various types of on-top-plasties have been described in the hand literature; these consist of transfer and distal advancement of composite soft tissue and bone segments from adjacent fingers. We prefer free transfers instead of these local transfers, which tend to require extensive dissection and lead to secondary contractures within the first web space (see Fig. 43-50).

TYPE IX THUMB HYPOPLASIA: FIVE-FINGERED HAND

Anatomy

In type IX hypoplasia the thumb is smaller in width and longer in length and has the characteristics of a finger. As the radial border digit, it lies in the same plane as the ulnar four digits and is nonopposable. It is usually the same length as the adjacent index finger. The digit is slender and may often be joined to the index finger in an incomplete simple syndactyly. A severe deficiency or nonexistent first web is often present. The skeletal anatomy is similar to that of the index ray. A metacarpal with a distal growth center and three phalanges with proximal growth centers are present. The scaphoid is usually absent or hypoplastic.¹²⁵ The thenar musculature (AbPB, FPB, OP muscles) is absent, as is the adductor pollicis (AddP). Instead, the usual digital intrinsic muscles are present: a lumbrical, palmar interosseous, and dorsal interosseous muscle (Fig. 43-52). The extrinsic flexors and extensors mimic those of the normal fingers. Because the radial digit lies in the same plane as the other fingers in the hand, manipulation of objects is usually performed by using lateral scissoring between the first two digits and between the second and third if a first web syndactyly is present. If first web syndactyly is left untreated, patients tend to attenuate the transverse metacarpal ligament and to “autopollicize” into an abducted and slightly pronated posture.

Fig. 43-52 Type IX thumb hypoplasia—five-fingered hand. **A**, In a five-fingered hand, the normal complement of median-innervated thenar intrinsic muscles is absent. The first dorsal interosseous, volar interosseous, and lumbrical muscles are present in this ray, which anatomically is a digit, not a thumb. **B**, The model of the preoperative clinical appearance (*left*) shows that the patient has tried to flex and autopronate this ray to become a thumb.

Management

The optimal management of these patients is to pollicize the radial digit. The technique employed is similar to that for thumb aplasia (type V).^{83,90,93} Like pollicization for thumb aplasia, rebalancing of the intrinsic musculature is paramount to the success of the procedure. In the five-finger hand anomaly, the dorsal interosseous to the radial digit is only unipennate, and secondary opponensplasty with an abductor digiti quinti muscle transfer is occasionally necessary.

Fig. 43-53 The thumb in a five-fingered hand. **A** and **B**, The right hand of a child with bilateral five-fingered hands; she has autorotated the radialmost digit into a pseudothumb position in an effort to function more effectively. **C** and **D**, In one procedure, the thumb was shortened and fused at the proximal interphalangeal joint, and a first web space was created with a radial forearm fasciocutaneous flap, which is seen before, during, and 5 years after the procedure. A superficial flexor tendon was transferred to improve palmar abduction (opposition). **E** and **F**, Five years postoperatively, there has been no contracture or diminution of this web space, which was lined with full-thickness flap tissue.

When type IX hypoplasia is seen late, two other options are available: construction for a first web space with a distally based forearm flap or free tissue transfer plus arthrodesis of the PIP joint, or a rotation-recession osteotomy of the first metacarpal with pollicization and intrinsic rebalancing (Fig. 43-53). This condition should not be confused with a triphalangeal thumb, in which the thumb is somewhat shorter than the other digits. Although an extra phalanx is present by definition, extrinsic and intrinsic muscle anatomy mimics a thumb more than a finger. The extra phalanx is commonly angulated. This is commonly associated with radial polydactyly.

TYPE X THUMB HYPOPLASIA: RADIAL POLYDACTYLY

Anatomy

Despite the level of duplication, each partner thumb is hypoplastic to varying degrees, with the radial duplicate usually being the most severely affected. The complexity of the deformity and therefore the surgical correction required increases as the level of the duplication progresses proximally. Associated triphalangia of the ulnar partner further complicates the surgical reconstruction. Specific abnormalities in each duplicate are seen in the nail plate, the osteoarticular column, and both the intrinsic and extrinsic myotendinous units of each thumb. The nail plate of each duplicate is always more narrow than that of the unaffected thumb. The entire skeletal ray is hypoplastic in duplications proximal to the MP joint. Myotendinous abnormalities are common, with the extrinsic extensor being almost universally shared.

Deviation of the partners toward each other indicates abnormal insertions of the extrinsic tendons into the distal phalanges. Connections between the extrinsic flexors and extensors are not unusual. These tendinous interconnections will limit function and cause digital angulations. The first web is usually unaffected in duplications involving the distal phalanx, but as the level of duplication lies more proximal, the first web space becomes increasingly deficient.

Management

The management of patients with duplications of the thumb will vary for the level of duplication and are discussed in more detail elsewhere in this book (see Chapter 46). In general, the surgeon should use the best parts of each thumb to construct the best possible thumb. Distal duplications (types I and II) are usually managed by preservation of the ulnar duplicate with extra soft tissue being provided from the radial thumb. The resulting nail is smaller than that on the normal side. The Billhaut-Cloquet procedure is avoided if possible because of the predictable problems of nail ridging and diminished IP joint motion.⁸² Duplications at the proximal phalangeal level (types III and IV) are also commonly managed with ablation of the radial partner and closure as required with tissue from this thumb. Myotendinous abnormalities need to be addressed with the division of interconnections and centralization of insertions. Advancement of the detached thenar intrinsics into the retained extensor mechanism is mandatory. Collateral ligament preservation and reattachment is key in providing a stable MP joint.¹²⁶ The metacarpal head will be broad in these patients and require trimming on the redundant radial side. A closing wedge osteotomy of the metacarpal may also be required to realign the newly constructed thumb. Appropriate trimming of excess skin should result in wound closure, which is positioned in the high midaxial position. Duplication in the metacarpal shaft (type V) can often be managed by simple ablation

of the radial partner and concomitant manta ray flap⁵⁹ or four-flap Z-plasty for any first web deficiency. Duplications at the CMC joint level (type VI) and triphalangeal varieties all need to be dealt with on their merit. Digital transposition of the ulnar thumb onto the retained base of the radial partner is not unusual. Skeletal realignment, tendon repositioning, and first web releases can usually be completed in a single stage.

TYPE XI THUMB HYPOPLASIA: SHORT SKELETAL RAY

Anatomy

Deficiencies of the osteoarticular column of the thumb may result in a short, hypoplastic thumb.⁶⁶ Bony abnormalities can occur as isolated findings (brachymetacarpia, brachyphalangia), all bones in combination, or as part of a generalized syndrome, such as the acrocephalosyndactyly syndromes (for example, Apert, Pfeiffer, Carpenter) or the Rubinstein-Taybi syndrome. Joint function is usually impaired on either side of the abnormal bone (or bones). In patients with anomalies of a single bone, brachymetacarpia or brachyphalangia, the remaining components of the thumb tend to be unaffected, and in patients with generalized syndromes, other abnormalities of the thumb components are common. In the acrocephalosyndactyly (ACS) syndromes, delta phalanges are usual. This typically involves the proximal phalanx, with a longitudinal epiphyseal bracket on the radial side. This abnormal growth plate checkreins growth on the radial side and results in a radial clinodactyly of the thumb. The metacarpal is usually short, and the distal phalanx is short and broad. Many surgeons think that the abnormal proximal phalanx and broad distal phalanx are variations of duplication. Myotendinous anomalies are associated with poor joint function. Deficiencies of the first web are most commonly seen in patients with Apert syndrome. This can be anywhere along a spectrum of mild adduction contracture to complex syndactyly involving the first two rays (Fig. 43-54).

The whole spectrum of patients with metabolic bone diseases, skeletal dysplasias, and tumors may include thumb hypoplasia. In general, very little surgical correction is required for these children.

Management

Many patients with short thumbs that are not associated with generalized conditions do not require any treatment, since the length deficiency is mild. In thumbs that do have an obvious length deficiency, distraction lengthening with a secondary bone graft to the subsequent bony defect at the metacarpal level is the treatment of choice.

Patients with generalized syndromes require a multidisciplinary approach to the management of that thumb, and hand procedures can be coordinated with other required treatments. Children with complex hand anomalies, such as those with Apert syndrome, require special attention to optimize the function in their hands. First web syndactyly needs to be managed in the first 3 to 6 months of life so that these children can develop with their thumbs released before the development of prehension. The deficiency of the first web in the majority of the children with cra-

Fig. 43-54 Type XI thumb hypoplasia—short skeletal ray. **A**, A short thumb with or without radial clinodactyly is seen in many syndromes. The primary osseous abnormalities are usually seen at the proximal phalangeal joint level. The median- and ulnar-innervated intrinsic muscles are all present and are very hypertrophied. Extrinsic and intrinsic flexors and extensors are normal up to the phalangeal level. **B**, The thumbs of children with four different syndromes all look similar: 1, Rubinstein-Taybi; 2, Pfeiffer; 3, Greig cephalopolysyndactyly; and 4, Apert acrocephalosyndactyly.

niosynostoses can be adequately treated with a manta ray flap or a four-flap Z-plasty. In the more complex type II and III hand anomalies in Apert syndrome, where there is complete syndactyly of the first web, we have found tissue expansion of the first web to be a very satisfactory means of producing a long-lasting release of the first web.³³ The deficiencies of length and angulation in these complex anomalies that are associated with a “delta” phalanx should be managed with an opening wedge osteotomy and iliac crest bone graft, or in Apert syndrome, the synostotic bone from the base of the fourth and fifth metacarpals. Because these bones are quite small, this procedure is usually delayed until 4 or 5 years of age^{66,82} (Fig. 43-55).

Fig. 43-55 Short thumb in syndromic patients. **A**, Preoperative appearance and thumb radiographs of a young boy with bilateral radial clinodactyly of the thumbs (“hitchhiker thumbs”) associated with Rubenstein-Taybi syndrome. **B**, The soft tissue was lengthened on the radial side with a large Z-plasty and a composite graft. The bone was lengthened, as seen here, with an opening wedge osteotomy and corticocancellous bone graft held with two C-wires. **C**, The same thumbs are seen 7 years later. The right side has grown normally, and on the left, the deformity has recurred because of the premature closure of the radialmost border of the growth plate.

KEY POINTS

- Congenital thumb differences are very common and are present to some degree in most syndromic categories, including constriction ring syndrome, symbrachydactyly, typical cleft hand, and radial polydactyly, among others.
- There is a wide spectrum of anatomic and functional deficiencies.
- A careful physical examination and identification of all soft tissue and skeletal deficiencies is the most important component in planning management of these children.
- The original German classification, which outlines five categories (types I through V), is most commonly used in clinical management.
- A moderate-to-severe deficiency of the first web space is the most commonly missed deficiency in these children. A simple release with local flaps is one of the most functional procedures done in pediatric hand surgery.
- Despite impressive refinements in microsurgery, pollicization is still the procedure of choice for the type IIIB thumb.

31. Entin MA. Reconstruction of congenital abnormalities of the upper extremities. *J Bone Joint Surg Am* 41-A:681, 1959.
This early article outlined the major categories within which congenital thumb anomalies are identified. Emphasis was placed on the importance of the thumb in hand function. The author noted that a "basic hand" must contain (1) a mobile, stable thumb on the radial side of the hand, (2) an intervening web space, and (3) one more digit or a post on the opposite side of this web.

37. Coombs CJ, Upton J. The hypoplastic and absent thumb. In Bentz ML, ed. *Pediatric Plastic Surgery*. Stamford, CT: McGraw-Hill, 1997.
This comprehensive analysis of thumb deficiencies focused on initial evaluation, planning of surgical treatment, well-executed surgery, and postoperative follow-up. For the first time in a major text, the thumb deficiencies seen in other groups of congenital differences were included. Microvascular options were covered in detail.

41. Blauth W. [The hypoplastic thumb] *Arch Orthop Unfallchir* 62:225, 1967.
The original classification system was described, starting with type I minimal deficiencies and ending with type V aplasia.

42. Blauth W, Schneider-Sickert F. Congenital Deformities of the Hand: An Atlas of Their Surgical Treatment. Berlin: Springer, 1981.
This original atlas was well illustrated with black and white drawings that clearly demonstrate reliable techniques of thumb construction or reconstruction. After review of this comprehensive yet concise atlas, a hand surgeon will realize that very few techniques believed to be new are really original.
43. Buck-Gramcko D. Hypoplasia and aplasia of the thumb. In Buck-Gramcko D, Nigst H, Millesi H, eds. Hand Surgery. Stuttgart: Thieme, 1981.
44. Manske PR, McCarroll HR, James M. Type III-A hypoplastic thumb. J Hand Surg Am 20:246, 1995.
In this paper a refinement of the original classification divides type III into two categories, depending on the presence or absence of the CMC joint. A careful postoperative analysis following various types of reconstruction was included. Thirteen type IIIA thumbs were reviewed.
45. Edgerton MT, Snyder GB, Webb WL. Surgical treatment of congenital thumb deformities (including psychological impact of correction). J Bone Joint Surg Am 47:1453, 1965.
This classic description of 11 patients with congenital thumb differences emphasized the anatomic variations of the hand, wrist, and forearm, surgical principles for reconstruction, and postoperative care. For the first time a psychological evaluation and analysis of the impact of these anomalies on these children was included. There was also a complete description for the authors' method of pollicization.
46. Buck-Gramcko D. Congenital Malformations of the Hand and Forearm. London: Churchill Livingstone, 1998.
47. Graham TJ, Louis DS. A comprehensive approach to surgical management of the type IIIA hypoplastic thumb. J Hand Surg Am 23:3, 1998.
This excellent review emphasized the careful anatomic evaluation and tailored treatment designed to correct the specific anatomic deficiencies. A discussion of the clinical evaluation and surgical approach of 14 type IIIA thumbs was included. Extended surgical incisions followed the various anomalies well up into the forearm. Emphasis was placed on first web space deepening, collateral ligament reconstruction, lysis of adhesions, excision of the pollex abductus anomaly, and opposition transfers.

Congenital Hand Anomalies: Failure of Differentiation

Robert J. Havlik • Patrick C. Hettinger

The American Society for Surgery of the Hand and the International Federation of Societies for Surgery of the Hand have developed a classification system for congenital anomalies of the upper extremity. In this system, failure of differentiation includes a broad group of disorders, including those involving soft tissue, those involving skeletal tissue, and congenital tumorous conditions. Failure of differentiation refers to anomalies in which the basic units have developed, but the final form is not completed appropriately (Boxes 44-1 and 44-2).

Within this broader group of disorders, syndactyly is the diagnosis of most interest to plastic surgeons. Most of this chapter focuses on the characteristics and the treatment of this anomaly. The other diagnoses considered failures of differentiation occur less frequently and the discussion of these is more limited in this chapter.

Box 44-1 Classification of Congenital Hand Anomalies: Failure of Differentiation (Separation) of Parts

Failure of Differentiation: Soft Tissue

Arthrogryposis

Arthrogryposis is a diverse group of disorders sharing common clinical characteristics. They are discussed in Chapter 50 and will not be discussed here.

Congenital Flexion Deformities of the Hand

A congenitally flexed position of the thumb may be a normal variant in an infant, but it may also be seen in many disorders, including congenital trigger thumb, congenital clasped thumb, and arthrogryposis. A physical examination is critical for establishing a proper diagnosis and guiding treatment, with detailed attention to the hand and the associated findings and syndromes. On the hand, the presence or absence of flexion and extension creases should be determined. These findings can indicate that a digit has never been flexed or extended. They also help to identify the level at which the flexion deformity of the thumb occurs. In many children, the long extensors of the thumb undergo a delay in maturation, leading to extensor weakness and resultant limited or absent thumb extension and abduction during early infancy, with flexion deformity at the level of the metacarpophalangeal (MP) joint. Children with congenital trigger thumb have a flexion deformity at the interphalangeal (IP) joint of the thumb. In contrast, children with congenital clasped thumb deformity have flexion at the MP joint level.

In children with apparently normal development but without thumb extension and abduction, the only treatment usually necessary is splinting the thumb in both extension and abduction. A forearm-based splint should be fabricated as soon as a deficiency in motion is noted. It should be worn 23 hours a day, allowing time for bathing and hygiene. Most of these patients respond favorably and completely as maturation occurs.

Congenital trigger thumb is common and relatively easily differentiated from congenital clasped thumb based on the level of the deformity. A trigger thumb is typically held in a flexed position at the joint, unlike the MP joint in a normal hand and the congenital clasped thumb noted later in the chapter. A trigger thumb may be truly congenital and evident at birth, or it can arise during early infancy. Once the digit is flexed, the child will generally hold it in this position, because the sensation of the triggering may be uncomfortable. Less frequently, the digit is held in extension at the IP joint of the thumb. A nodule (Notta node) may be palpable just proximal to the thumb flexion crease. The role of splinting in this disorder is controversial; some authors recommend it, and others think it is not beneficial. Treatment is guided by the knowledge that, in some series, the disorder spontaneously resolved.^{1,2} Surgery should be deferred until the child is at least 9 to 12 months of age to allow spontaneous resolution. If the lesion persists, surgery is carefully performed to prevent injury to the digital sensory nerves that lie more centrally in the thumb relative to the other digits. A transverse incision is made at the proximal thumb palmar flexion crease just through the dermis. The digital sensory nerves are identified, and the A1 pulley is completely released along the radial aspect. Full excursion of the thumb without restriction should be demonstrated before closure.

The treatment for flexion deformity at the MP joint depends on associated findings. As noted previously, if the child is otherwise normal, the flexion deformity may result from a simple delay in maturation and extensor system weakness, which will respond to splinting. These children need continued follow-up, because the flexed posture may indicate a congenital clasped thumb.

Congenital clasped thumb can be categorized into two groups: supple and complex.³ The supple subtype often has only a deficiency of the extensor mechanism, whereas the complex type also has a variable degree of MP joint contracture, collateral ligament abnormality, thenar muscle hypoplasia, web space tightness with skin deficiency, and flexor pollicis longus tightness. Complex congenital clasped thumb can be an isolated deformity, but it often occurs in association with other deformities, including arthrogryposis. Clasped thumb deformity associated with arthrogryposis is discussed in Chapter 50.

Syndactyly

Syndactyly is derived from the Greek “syn,” meaning *together*; and “dactylos,” meaning *digits*. Syndactyly is one of the most common congenital anomalies involving the hand and upper extremity.⁴ In most large series of congenital anomalies of the upper extremity, the three most common anomalies of the upper extremity are syndactyly, polydactyly, and camptodactyly.⁵ The differences in the incidence of these three anomalies may largely reflect the patient series and the population studied, rather than a true variability in the overall incidence.⁵ For example, polydactyly is much more common among African-Americans, in whom it is transmitted in autosomal dominant fashion. Overall, the incidence of syndactyly in the general population is estimated to be one in 2000 births.^{4,6,7} In England and Wales,⁸ where the British National Health Service provides comprehensive population-based health statistics, the incidence of syndactyly in the British population is approximately one in 1725 births. In more than 95% of all pregnancies carried to term in the United States, the infant is “normal,” and the most common major congenital anomaly is orofacial clefting (cleft lip and/or cleft palate), which has an incidence of approximately one in 700 births.⁹ If the incidences of syndactyly, polydactyly, and camptodactyly are nearly equal, then their combined incidence is roughly the same as that of orofacial clefting.

Many classification schemes have been proposed for syndactyly. Some group entities together and some further divide them into subcategories. One of the most widely used is a simple four-category system. In this classification scheme, syndactyly is characterized as *complete* or *incomplete*, based on the extent of webbing present between the digits, and as *simple* or *complex*, based on the presence or absence of bony union. In complete syndactyly, the webbing extends all the way distally to involve the fingertips, whereas in incomplete syndactyly the webbing extends to any-

Fig. 44-1 A, Simple complete syndactyly. B, Simple incomplete syndactyly. C, Apert rosebud type III hand with complex syndactyly (see Apert Syndrome: Acrosyndactyly section later in the chapter).

where between the fingertips and the normal position of the web space (Fig. 44-1). Although the normal position of a web space varies, generally, the most distal aspect of the web space lies on the palmar aspect of the hand, at a point halfway between the metacarpal head and the proximal phalangeal head.⁷ *Simple syndactyly* refers to cases in which the digits are joined by only the skin and fibrous tissue of the hand, whereas *complex syndactyly* also involves a coalition between the bones of the phalanges (see Fig. 44-1). The usefulness of this classification system lies both in its simplicity and its large descriptive groups, which are helpful to many physicians.

As a research classification system or as a system of precise communication between physicians who treat these disorders frequently, this rudimentary classification system is less useful. Syndactyly can vary tremendously across a spectrum, sometimes involving abnormal connections between tendons, nerves, and arteries. Surgeons need to understand that these abnormal connections occur, recognize them, and define and treat them accordingly. Syndactyly can also be a manifestation of other syndromes, such as Apert syndrome or Poland syndrome. In pseudosyndactyly, the digits were once completely separated but are drawn back together, as in constriction ring syndrome (amniotic band syndrome) or dystrophic epidermolysis bullosa. These special circumstances will be discussed separately later in the chapter. The following discussion pertains to nonsyndromic syndactyly.

SYNDACTYLY

Genetics, Etiologic Factors, and Embryology

Syndactyly occurs in approximately twice as many males as females and most often involves the long-ring web space of the hand and the second-third web space of the foot. The long-ring web space is affected in 50% of all cases.⁷ The ring-small web space is involved in 30% of cases, the index-long web space is affected in 15% of cases, and, generally, the thumb-index web space is spared, involved in only 5% of cases.⁴ Approximately half of all cases of syndactyly are bilateral. Most are sporadic, isolated anomalies. However, 10% to 40% are inherited on a familial basis. The large variation in familial inheritance is probably dependent on the population sample studied. Flatt⁴ reported a familial incidence of 40% in his population of 413 patients with syndactyly. This relatively high rate of familial occurrence may be related to the large, stable population in Iowa that made up his reference population. All patterns of genetic inheritance have been postulated based on retrospective pedigree analysis, and the most common pattern is autosomal dominant with incomplete penetrance.⁶

In normal development, the hand plate develops from approximately week 5 to week 7 of gestation.^{5,10,11} Hand development is driven by diffusion of growth factors in local tissues, creating local concentration gradients. The hand plate develops five ridges that are the digital precursors. These ridges develop by programmed cell death, or apoptosis, of the apical ectodermal ridge in the areas between the ridges, typically at 48 days of gestation^{5,11} (Fig. 44-2). The process of apoptosis starts distally and progresses proximally. Concurrently, the mesenchymal tissue in the ridges and digital buds undergoes continued condensation and growth. Digital separation is completed by programmed cell death of the intervening tissue, typically at 51 days of gestation¹¹ (see Fig. 44-2). By 8 weeks of age, the digits have developed touch pads distally, and the hand's appearance is largely defined¹¹ (see Fig. 44-2). The failure of separation of the digital rays causes syndactyly. This pattern of morphogenesis may account for the relatively low incidence of involvement of the first web space, because the thumb ray is known to separate from the rest of the hand earlier in this process of differentiation. However, we do not know how this mechanism leads to the male

predominance of the disorder or the predominant site of involvement—the first postaxial web space in the foot and hand (the second-third toe space and the ring-long web space of the hand).

Functional Implications and Timing of Surgery

Depending on its location within the hand, syndactyly may have limited impact on overall hand function and development. Therefore the timing of separation of the digits in syndactyly depends on the digits that are affected and the extent of overall involvement of the hands. Developmentally, the ability to position the hand in space (a cortical function) and the development of grasp are established by a year of age.¹² The ability to position the hand and use effective grasp undergoes continued refinement to 3 years of age. Therefore, in cases involving the thumb and index finger, separation of the digits and the creation of a sufficient first web space are desirable at an early age (younger than 6 months). Cases that involve the ring-little or thumb-index web spaces (border digits) require earlier separation because of the inherent length discrepancy between the thumb and index fingers and the ring and little fingers. Failure to separate these digits before 6 months of age can lead to permanent distortion of the longer finger (index finger and ring finger, respectively) as it is held back by the tethering force of the shorter finger. In complex syndactyly, in which the digits are conjoined with bony fusion between the distal phalanges, earlier separation is needed to prevent deformation of the digits with growth. For hands with multiple digital involvement, planning an appropriate course of treatment is imperative. Treatment should allow timely separation between border digits and completion of the process within the first few years of life. This is especially true in Apert hands, in which digital separation must be coordinated with craniofacial operations. An additional advantage of early surgery in these complex cases is that bilateral surgery can be performed and is usually well tolerated until patients are 1 year of age. This minimizes the number of anesthetics and independent operative procedures that a child must undergo.

In contrast, separation of the most common digital syndactyly involving the long finger and ring finger web space can be deferred until the child is older without significant functional sequelae. However, social issues begin to become a significant issue by school age. Separation should be completed before this to prevent ridicule and social ostracism.

Goals and Principles of Surgery

Three primary goals are considered when planning the approach for reconstructing a hand with syndactyly: (1) allow the patient to position the hand (and fingers) in space; (2) provide adequate and sensate skin coverage; and (3) provide a satisfactory power grasp with the ability to handle objects precisely.⁴ Six primary tenets of reconstruction of syndactyly help to ensure that these goals are met:

1. All osseous and soft tissue between the digits should be separated.
2. The nerves and the vascular supply are optimally preserved.
3. An adequate web space is established between the digits by developing a flap of appropriate length that is inset without tension.
4. Interdigitating flap coverage is provided over the mid-lateral digit, ideally at the level of the PIP joint.
5. Appropriate distal phalanges are developed.
6. Perforated, full-thickness skin grafts are used to minimize the effects of secondary wound contraction on the lateral aspect of the phalanges.

The treatment paradigm for the separation of complete and incomplete syndactyly is very similar in all digits, except for the thumb-index web space, which is discussed separately.

Separation of the digits includes separation of the conjoined dorsal and palmar skin, subcutaneous fat, conjoined ligaments, and sites of osseous union, while preserving the integrity of the nerves and blood vessels. When separating the skin, care is taken to optimize the digital coverage

Fig. 44-3 Cross-section of a digit showing the location of Cleland ligaments.

with skin and to resurface the web space, as described later in the discussion. The subcutaneous fat is usually moved en bloc with the overlying skin. In virtually all syndactyly, simple or complex, complete or incomplete, conjoined ligaments exist between the digits. These are probably conjoined sections of Cleland ligaments (Fig. 44-3). In normal digits, Cleland ligaments usually provide points of fixation of the skin to the underlying skeleton of the digit in the mid-axial line of the digit. This provides stability of the skin during grasping and digital manipulation, and it transfers the force imparted by the musculoskeletal units to grasp the object in hand and resist shear stresses. In syndactyly, the coalition between these structures results in the strong fibrous union between the skeletal framework of the digits, and this must be divided. Complete separation of these ligaments is essential, with preservation of the underlying neurovascular bundles. It is seldom, if ever, necessary to extend the division of these deep soft tissues more proximally to include the division of the transverse metacarpal ligament.

In normal anatomic relationships, the neurovascular bundles lie just palmar to this area of ligamentous union. Separation of the neurovascular bundles requires meticulous attention to the anatomy. Distal bifurcations of the blood vessels may be encountered, and if they are too distal to allow appropriate separation of the digits, two precautions are appropriate:

1. It is generally accepted that only one side of a digit be separated at each operative session. Surgeons should not attempt to separate both sides of a digit for concern of vascular disruption or vascular spasm.
2. If the vascular integrity of a digit is in question, a microvascular clamp should be placed distal to the bifurcation of the digital artery at the contemplated site of division of the digital artery and the tourniquet released. Vascular perfusion to the digit should be sufficient before the proper digital artery is ligated.

In contrast, nerves generally pose less of a problem than the vascular supply. A distal branching of the digital nerves can be separated bluntly with the back of a scalpel blade or the closed points of tenotomy scissors. Appropriate length of the nerves can almost always be gained by these relatively simple techniques.

Creating an appropriate web space and commissure between digits is essential for separating digital syndactyly. Flaps are always preferable to grafts in this location for their suppleness and pliability. The web space must be soft and supple to facilitate digital motion without irritation from unstable skin coverage. In addition, placing a soft, supple flap of tissue will minimize the chance of distal migration of the web space with further growth of the hand. Several flap designs for creating and resurfacing the web space have been promoted over the past 100 years, includ-

Fig. 44-4 Dorsal hand flap design extending two thirds of the distance between the metacarpal heads and the PIP joint.

Fig. 44-5 Separation of syndactyly always involves a net skin deficiency. The available skin measures only four times the radius ($2r$ above and $2r$ below), whereas the surface area to be covered equals $2\pi r$ (πr on the medial aspect of each finger).

ing dorsal flaps, palmar-based flaps, and various combinations of these flaps in interdigitating patterns. Ideally, the web space has a dumbbell-shaped surface, with a narrower waist and wider dorsal and palmar components. It should be sloped from proximodorsally to distally in the palm, replicating the normal anatomy. Perhaps the most widely used design is that of a dorsal web flap described more than 50 years ago by the Indiana plastic surgeons Bauer, Tondra, and Trusler¹³ (Fig. 44-4). This technique has the advantages of creating a flap of appropriate width, length, and dorsopalmar slope in a reliable manner and of leaving the web space largely devoid of scar tissue that could create secondary contracture. The disadvantages are that it leaves areas on the opposing sides of the adjacent proximal phalanges that require grafts, and that it creates a linear palmar scar at the junction of the web with the palmar skin that may in some cases lead to a secondary contracture across the palmar junction of the web. Upton⁵ proposed a modification that employed a small palmar-based triangular flap to interdigitate with the large dorsal flap. This small flap has two advantages. It breaks up the linear palmar scar and may limit secondary linear contracture, and it adds breadth to the palmar aspect of the web space by expanding the width of the palmar end of the web flap.

In the separation of syndactyly, skin coverage is always deficient (Fig. 44-5). In addition, the use of a large dorsal flap to create the web space leads to tissue deficiency on the dorsal and lateral aspects of adjacent proximal phalanges. The site of the separation of the digits must be resurfaced. We do not agree with the recommendation of several authors that the skin flaps should be preferentially used to resurface one of the two digits, with graft applied to the other.⁴ The design of the skin and subcutaneous flaps should ideally allow the creation of triangular flaps that provide coverage at the level of the PIP joint. Depending on the extent of tissue deficiency, either complete or partial interdigitation is possible. With a skin flap design, this is possible in virtually all cases, with the possible exception of the severe tissue deficiency seen in Apert hands. This approach has two major advantages. First, it provides soft and supple, well-vascularized skin over the joint of the finger that has the highest demands for range of motion. The PIP joint typically has a range of active motion of 135 degrees. The second advantage is that this approach divides the area of full-thickness graft necessary to much smaller areas. Hand surgeons acknowledge that

Fig. 44-6 A, Interdigitating flaps are drawn on the hand hyponychium to create digital paronychium after separation of the nail plate (after Buck-Gramcko). B, Interdigitating flaps for reconstruction of the paronychium.

Fig. 44-7 Potential skin graft donor sites for grafting for syndactyly. X marks the anterior superior iliac spine.

any area of graft loss should promptly undergo repeat grafting. This is much easier with smaller areas as opposed to the entire side of a digit.

Separation of the distal phalanges is an important component of separation of digits, and one that requires a well-planned and thorough approach for success. In complete syndactyly, the degree of tissue deficiency guides the approach. Cases of complete syndactyly that do not include a conjoined nail plate have a rim of paronychial tissue. Separation can often be followed by simple advancement and closure of the pulp skin and subcutaneous tissue to this rim of paronychial tissue. If the nail plate is fused, advancement and closure are occasionally possible, but the alternative of interdigitating incisions on the hyponychium should be considered¹⁴ (Fig. 44-6). These incisions create flaps that can be brought proximally to create a functional paronychial reconstruction.

After a web space is created, the distal phalanges are reconstructed, and interdigitating flaps are brought into either alignment or abutment at the proximal phalangeal level. Areas are always

present that require resurfacing with skin grafts. Full-thickness skin grafts are used. These can be harvested from the groin, the medial upper arm, the lower abdomen, or even the foreskin (Fig. 44-7). Areas not to use as donor sites include the palmar wrist and the antecubital fossa, both of which leave considerable unsightly scarring. As Netscher¹² has appropriately pointed out, in children of color, skin grafts tend to hyperpigment, and the dark grafts can be unsightly. Therefore he recommended the use of the light-colored skin from the side of the foot before the child begins to ambulate to provide an appropriate color match. This approach has merit.

Surgical Technique

After anesthesia is given, the upper arm is wrapped with cotton batten or a cotton sleeve, and a tourniquet is placed on the upper arm. Positioning the child's torso on an arm board perpendicular to the main operative table is often helpful. In standard fashion, all intravenous lines, cables, and bipolar cautery are routed away from the end of the hand table so that the end of the hand table is unobstructed. In bilateral cases, a double extremity sheet is useful for draping the child (Fig. 44-8, *A*).

All surgery is performed under loupe magnification. The digits are drawn into flexion, and operative markings are made. The center position of the metacarpal heads is marked on the skin (see Fig. 44-4). The dorsal flap is designed as a trapezoid, extending from the midpoint of the metacarpal heads to a transverse line approximately two thirds to three fourths the distance to the dorsal PIP joint. The flap should be long enough to be transposed to create a new commissure without tension. The level of inset of the flap is then designed on the palm with a transverse line marked at a point 3 to 4 mm proximal to the alignment of the normal cascade of the web spaces (Fig. 44-8, *B*). Normally, the position of the index-long web is at the same level as the long-ring web, whereas the ring-little web is more proximal. This transverse line marking the palmar aspect of the web space is usually placed at a point proximal to the proximal digital crease. Although it is debatable, overcorrection by placing the palmar position of the web space 3 to 4 mm more proximally than the native arcade of the web spaces is reasonable and allows a margin of distal web creep with hand growth. A triangular-based flap can be designed with the base on this transverse line to allow interdigitation with the dorsal flap.⁵

The next step is to plan the closure of the lateral aspects of the digits. A V-shaped flap is designed on the dorsal skin of the hand and a V-shaped flap on the palmar surface of the hand that are based on opposite digits. The apices of the flaps extend approximately halfway across the digit. The adjacent distal flaps are similarly designed to facilitate interdigitation of the flaps and flap approximation at the level of the PIP joint (Fig. 44-8, *C* through *E*).

In complete syndactyly, the design for separating the distal phalanges and the nails is the next step. This uses either advancement of the palmar skin and soft tissue pulp or the interdigitating incisions and flaps developed by Buck-Gramcko¹⁴ (see Fig. 44-6). The dorsal interdigitating flaps between the distal phalanx and the PIP joint are designed, followed by the palmar design of the interdigitating flaps. In this design phase, the priority is to obtain the following:

- Favorable commissure resurfacing
- Optimal resurfacing of the distal phalanges
- Interdigitating flap coverage that reaches across each digit at the level of the PIP joint (see Fig. 44-8, *C* through *E*)

After completion of the flap design, the arm is exsanguinated and the tourniquet inflated to 200 to 225 mm Hg. The incisions surrounding the dorsal flap are made, and the dissection is performed

*Continued*

Fig. 44-8, cont'd **G**, Elevation of the dorsal flap reveals conjoined ligaments (consistent with fused Cleland ligaments) on the medial aspects of the digits. Starting distally, these ligaments are carefully divided under direct vision. The neurovascular bundles will lie immediately palmar to the conjoined ligaments, as shown in the cross-sectional diagram on the right, necessitating great care in identifying and preserving these structures. If they are not identified after the division of the first distal portion of the conjoined ligaments, attention is directed proximally, where they should be identified near the web space. The division of this thin layer of conjoined ligaments should proceed from proximal to distal. **H**, Progressive division of conjoined ligaments extends into the level of the web space. Division of the transverse metacarpal ligament is neither necessary nor desirable. **I**, Syndactyly separation after transposition of the web space flap and interdigitating flaps. The intervening areas and the donor site for the dorsally based web flap will require grafting. **J**, The shaded areas are common areas of tissue insufficiency that require grafting. **K**, It is desirable to limit and divide the areas into subunits with flaps (*bottom*) and less desirable to graft large, single areas (*top*). The use of interdigitating flaps over the PIP joint allows the graft to be divided into two smaller areas. **L**, Dorsal view and **M**, palmar view at the nine-month postoperative photographs showing healed syndactyly.

down to the level of the conjoined Cleland ligaments. The dorsal flap is elevated with the subcutaneous fat in the plane directly above the conjoined Cleland ligaments to the level approaching the metacarpal heads (Fig. 44-8, *F*). As the dorsal flap is elevated, care is taken to preserve some tissues over the lateral bands and the dorsal tendon, as well as the venous channels in the flap as much as possible. The veins often become evident as the subcutaneous fat is separated by blunt dissection with tenotomy scissors (see Fig. 44-8, *F*).

Distally, incisions for the flaps to separate the distal phalanges are made. If the interdigitating incisions of Buck-Gramcko¹⁴ are used, they should be made first, preventing injury to the bases of the flaps as the conjoined nail is divided (see Fig. 44-6). Attention is turned to the dorsal surface. The V-shaped flaps are incised and elevated off of the underlying conjoined ligaments (Fig. 44-8, *G*). The conjoined ligaments are divided along the entire length of the syndactyly, from distal to proximal (Fig. 44-8, *H*). The semitranslucent conjoined ligaments can be divided as the neurovascular bundles are identified. If these are not readily identified distally, the conjoined Cleland ligaments are divided at the level of the proximal phalanges, and the neurovascular bundles can be reliably identified at the level in the web and then traced distally to ensure their integrity is preserved. The palmar skin is sequentially incised, verifying the position of the premarked palmar flaps for interdigitation with the dorsal flaps as the division proceeds proximally. The incisions may be manipulated either slightly proximal or slightly distal to maximize coverage at the PIP joint. Next, the web space incision is made approximately 4 to 5 mm proximal to the proximal digital crease, and the dorsal flap is transposed into place and sewn with plain gut suture. The interdigitating flaps are transposed and secured in place (Fig. 44-8, *I*). Thinning the flaps is not usually necessary or desirable; instead, they are moved en bloc with their subcutaneous fat. The flaps are carefully positioned to ensure they are under minimal tension to prevent compromised perfusion. If this is in doubt, the interdigitation of the flaps should be relaxed with less advancement and the surface area to be grafted expanded to promote perfusion.

After transposition of the flaps, a template for assessing the surface area is made based on the size of the defect (Fig. 44-8, *J* and *K*). The tourniquet is released, and the perfusion and viability of the flaps and the digits are assessed. If perfusion and viability are questionable, the interdigitating flaps should be recessed and relaxed with a concomitant expansion of the area to be grafted.

The template is transposed to the donor site. In single digit separations, this is often the groin crease or the lower abdominal wall. In multiple digit separations, the donor site of choice is usually the lower abdominal crease, which has the advantage of providing a large volume of skin with relative ease and minimal tension on closure. Subcutaneous fat is harvested with the graft and defatted on the back table. The graft is thinned to the dermal level with scissors, and perforated or pie-crust by placing it on a folded paper surgical drape and perforating it repeatedly with a No. 15 blade. The donor site is closed in layers and completed with a subcuticular closure and tissue glue. Tissue glue provides an effective barrier while the infant is in diapers.

The perforated graft is tailored and secured under mild tension to the digit using interrupted sutures of plain or mild chromic suture. The interrupted sutures facilitate evacuation of blood from beneath the graft. Running sutures do not allow blood or serum to be evacuated from beneath the graft. Tourniquet time should be minimal (less than 2 hours).

The dressing is very carefully applied, beginning with bridal veil (for example, N-Terface or Dermanet) and a petrolatum ointment. A petrolatum gauze (Vaseline gauze or Xeroform) is then placed as 1-inch-wide strips around 270 degrees of each digit, centered on the site of digital separation and extending onto the adjacent digit. The web space is filled with moistened cotton batten and fluffed cotton gauze. One-inch polyester silk tape is then placed in a noncircumferential fashion, anchoring the web space dressing to the skin of the forearm and upper arm. Alternatively, in isolated cases, if small areas of graft are placed, they can be secured with tie-over bolster dressings using interrupted silk sutures to secure bridal veil, Vaseline gauze, and cotton

batten. In either case, a bulky hand dressing is then applied with fluffs and cotton gauze roll as a wrap. The tips of the digits should be visible at the distal end of the dressing. Three-inch silk tape is then applied to secure the dressing to the proximal forearm and upper arm. A fiberglass or plaster splint is placed to stabilize the hand, forearm, and elbow, with the elbow in 90 degrees of flexion. A stockinette dressing is applied as a swath around the torso. This elbow is carefully wrapped below the contralateral axilla to prevent pressure on the neck. The purpose of this extensive dressing is to secure the grafts to the bed. One manner in which this is achieved is by completely eliminating functional use of the hand, preventing the child from reaching for things. Effective immobilization is crucial to successful graft take and survival (Fig. 44-8, *L* and *M*).

First Web Space

The web space between the thumb and index finger is seldom involved in a true syndactyly in nonsyndromic patients (approximately 5% of cases).⁴ However, the first web space can often be constrained and restrict thumb motion, limiting the span of the hand's grasp and thumb function in congenital disorders. The first web space is critical to the function of the hand and the ability to position the thumb in space, thereby allowing effective grasp. In a normal hand, the thumb accounts for approximately 40% of total hand function (based on amputation at the MP level of the thumb [AMA guide]).¹⁵ In hands with limitations in other digits related to congenital anomalies, the thumb may contribute an even greater component to total hand function. The normal range of motion for the thumb in adults is 50 degrees of radial abduction, 8 cm of opposition (measured from the palmar surface of the thumb to the palmar surface of the base of the long finger in direct opposition), and 8 cm of adduction (the thumb tip to the MP joint of the fifth finger).¹⁵ Adduction contracture is considered significant if the intermetacarpal opening is less than 40 degrees.^{15,16} It is evident that a constrained first web space will affect function in all of these motions and significantly limit hand function. Cases with limited restriction can be treated by instructing the parents in range-of-motion exercises in which stress is isolated to the intermetacarpal space of the first web and performed several times per day. Splinting has not proved particularly beneficial in these children.¹⁶

Release of the first web space varies with the severity of the limitation caused by the restriction. In many cases, the only deficiency is the skin and subcutaneous tissue that creates a tethering effect on the thumb. Several techniques have been described for effective resurfacing of the first web space once a release is performed. All techniques make preferential use of adjacent and remote flaps, as opposed to skin grafts, to resurface the web expansion. The techniques create a gradual U-shaped web, not a steep V-shaped web. For this reason, double Z-plasties are preferred over a single, large Z-plasty. Three primary techniques using Z-plasty are routinely performed. These include a four-flap Z-plasty, a double Z-plasty, and a double-opposing Z-plasty (Fig. 44-9, *A* through *C*). These techniques are the workhorses for expansion and resurfacing of the first web space for moderate expansions. The technique chosen depends on the surgeon's experience and preexisting scars or anomalies that may limit the flap design. Larger expansions of the first web space, which may be necessary for severely constrained first web spaces in Apert syndrome, Poland syndrome, or arthrogryposis, may require dorsal hand rotation flaps.¹⁷ An expansion of the first web space by surgical release should not be compromised by resurfacing with an inadequate surface area of skin or a tight closure.

Additional measures may be needed for cases in which the first web space has a significant and severe adduction contracture. After the skin flap is elevated, the first dorsal interosseous muscle is identified spanning the dorsal web space. The initial step is to release the myofascia investing the first dorsal interosseous muscle. Motion is reassessed, and if the restriction persists, the origin

Fig. 44-9 A, Four flap Z-plasty for opening the first web space. B, Double Z-plasty for opening the first web space. C, Double-opposing Z-plasty for opening the first web space.

of the first dorsal interosseous can be partially released from the first metacarpal shaft, and the myofascia investing the adductor pollicis can be released. Great care is required for identifying and preserving the radial digital nerve of the index finger and the ulnar digital nerve of the thumb throughout this portion of the surgery. In severe cases, the insertion of the adductor pollicis can be detached and shifted more proximally on the thumb. The muscle body of the adductor should be protected, because it becomes the primary remaining muscle allowing effective pinch and grasp. Sometimes release of the muscle fascia and/or recession of the muscle or muscles is necessary to

adequately expand the first web space. In these cases, many hand surgeons will place a subcutaneous pin across the web space between the index and thumb metacarpal shafts to maintain the width that has been gained during the healing period to prevent contracture.

Alternative Surgical Approaches to Syndactyly

Although a dorsal-based web flap for commissure reconstruction is perhaps the most frequent approach used in contemporary management of syndactyly, other approaches have been advanced recently. Several of these advocate the use of a dorsal metacarpal flap to line the web space, thereby minimizing or eliminating the need for skin grating. Sherif¹⁸ recommended the use of a V-to-Y advancement dorsal metacarpal flap, and Hutchinson and Frenzen¹⁹ have reported additional experience with a comparable flap. Hsu et al²⁰ have modified this flap design to obtain a more favorable web configuration. Rather than V-Y advancement, Aydin and Ozden²¹ advocated rotating a dorsal metacarpal flap into the web space. These techniques have the advantage of allowing digital resurfacing in select cases without the use of skin grafts, have been shown to be reliable, and can be completed in comparable times; however, they result in a linear dorsal hand scar.

SPECIAL CONSIDERATIONS

Poland Syndrome: Symbrachydactyly

Poland syndrome is an uncommon deformity of the hand, arm, and chest wall that occurs in approximately 1 in every 25,000 births.^{22,23} The most often seen manifestation is a deficiency of the sternal portion of pectoralis major muscle, with preservation of the clavicular head of this muscle.^{24,25} Frequently, maldevelopment of other muscles of the shoulder girdle, deficiency of the subcutaneous tissue, anomalies of the ribs, and breast anomalies are present. In many females, the breasts do not develop at puberty and remain hypoplastic. The entire upper extremity may be slightly hypoplastic. The hand anomaly that typically exists in Poland syndrome is symbrachydactyly—shortened fingers that are fused together. The thumb is frequently involved and may have a constrained first web space. These digits are separated following the principles described previously. However, two important caveats exist. First, the neurovascular bundles frequently divide distally, and this must be anticipated in treatment planning.¹⁴ Second, the timing of separation of the fingers may need to be delayed, because the phalanges may be hypoplastic and the joints unstable. Delaying the separation will allow further growth of the digits and may lead to improved digital stability at the separation. If the digits remain hypoplastic and unstable, the benefits of separation of the syndactyly will be limited.¹⁶ However, the first web space can be released and resurfaced earlier and is not generally subject to this same consideration.

Apert Syndrome: Acrosyndactyly

Apert syndrome is characterized by severe, complex syndactyly involving the hands and a severe craniofacial malformation. It occurs in approximately one of every 150,000 births.²⁶ The disorder has been localized to an anomaly in the fibroblastic growth factor receptor. Unlike other mutations that lead to decreased binding between hormone and receptor, it is thought that the mutation in the fibroblastic growth factor actually leads to an increased binding affinity between the receptor and fibroblastic growth factor, signaling the downstream intracellular effects that lead to Apert syndrome.

Hand involvement in Apert syndrome can be grouped into three separate types:

Type I: *Obstetrician's* or *spade hand*, in which the thumb and fifth finger are largely free

Type II: *Mitten* or *spoon hand*, in which the thumb is typically joined to the hand mass by a simple syndactyly

Type III: *Rosebud* or *hoof hand*, in which the thumb is joined by a tight osseous or cartilaginous union to the finger mass²⁶ (see Fig. 44-1)

All cases typically have a complex union of the index, long, and ring finger distal phalanges. Apert syndrome is a complex anomaly and is discussed in detail in Chapter 45. It is mentioned here, because the syndactyly present in these hands is frequently severe, with significant anomalies of the tendons, nerves, and arteries. Distal division of the arteries and nerves are present routinely. The soft tissue deficiency is profound and may require flap coverage.

Pseudosyndactyly

Constriction Ring Syndrome

Constriction ring syndrome, also known as *amniotic band syndrome*, is a well-known anomaly that affects extremities and the face more frequently than the trunk. The condition is sporadic and not inherited. The overall incidence is approximately 1 in 15,000 births.²⁷ The cause of this disorder has been contentious. Some authors have reported that an intrinsic defect of the mesodermal

Fig. 44-10 A, Constriction ring syndrome demonstrating distal fusion of the fingers after digital separation. B, Epithelium-lined sinus tracts in constriction ring syndrome.

Fig. 44-11 A, Constriction ring syndrome with ischemic digits in the perinatal period of this premature child. B, A semicircumferential release with Z-plasties was performed under an operating microscope. Perfusion was improved. The second stage of the release was deferred until the child was older (about 6 months of age).

tissue leads to the characteristic constriction rings.²⁸ Today, most authors think that constriction rings are caused by external forces, such as amniotic bands, that encircle and/or compress areas of the fetus and lead to the characteristic deformities. Evidence for this includes a straight line across multiple digits, the presence of a filamentous structure often wound around the structure, and acrosyndactyly in which the digits that have been separated have apparently undergone re-fusion at the site of the band²⁷ (Fig. 44-10, *A*). The hallmark of these hands is the presence of fully lined sinus tracts that pass proximal to the site of distal digital fusion (Fig. 44-10, *B*).

Occasionally, constriction rings lead to ischemia and/or amputation. If this situation is evident at birth, prompt release of the band and Z-plasty is indicated (Fig. 44-11). Separation of the digits involved in constriction ring syndrome is directly analogous to syndactyly separation. Although Buck-Gramcko¹⁴ reported no complications using a single-stage total circumferential release, most surgeons recommend a staged, semicircumferential release. Constriction ring syndrome is discussed in detail in Chapter 49.

Epidermolysis Bullosa

Recessive dystrophic epidermolysis bullosa is an inherited skin disorder manifest by severe blistering disease of the skin and mucosal surfaces in response to mild trauma. The disease is characterized ultrastructurally by cleavage beneath the basal lamina and marked collagen degeneration of the papillary dermis in early blister formation.²⁹ Trauma, even a minor shear stress of the skin, leads to substantial sloughing of the skin. The hand becomes involved because of its position and propensity for trauma. The repeated slough and healing cycles lead to the formation of the regenerating skin that encases the fingers in a pseudosyndactyly, referred to as an *epidermal cocoon*. Treatment requires surgical separation of the digits and grafting, but the disorder is extremely prone to recurrence. Some authors have attempted to use alternative means of tissue coverage, but this experience is limited.³⁰ Care is needed to prevent trauma at all sites, including the oral and pharyngeal mucosa during anesthetics.

Camptodactyly

Camptodactyly, as noted previously, is one of the most common congenital anomalies of the hand.^{4,5} It is a descriptive name for a nontraumatic flexion deformity of the digit, most commonly the little finger; however, multiple fingers can be involved. The typical findings are flexion at the PIP joint with hyperextension of the MP joint.³¹ Most cases arise during the first year of life, but a smaller group of predominantly females will develop camptodactyly during adolescence.³² Approximately two thirds of the cases occur bilaterally.³³ Camptodactyly is often asymptomatic. The disorder is painless. The exact incidence is difficult to establish, because the disorder is probably underreported; however, one author has estimated that it affects less than 1% of the population.³⁴ Most mild cases are ignored by the child and by the parents, but the disorder can be severe, with the development of fixed contractures at the PIP joint, and can even be accompanied by rotatory deformity of the fifth digit into supination.³¹ If left untreated, most cases show some progression, particularly during periods of growth.³¹

Camptodactyly describes the posture or position of the finger and does not indicate a discrete diagnosis or pathogenesis. Many cases of camptodactyly occur sporadically, whereas others are autosomal dominant. Some are related to congenital syndromes, such as trisomy 13, oculodentodigital syndrome, orofacial digital syndrome, Aarskog syndrome, and cerebrohepatorenal syndrome.³¹ The factors possibly contributing to camptodactyly are numerous and varied. Most of the structures in the hand and finger have been suggested as contributors, including aberrant

lumbrical muscles, a band of palmar fascia from the A1 pulley, a band of fibrous tissue in association with the Landsmeer ligament, PIP palmar plate contracture, laxity of the extensor mechanism at the dorsal PIP joint, and anomalies of the flexor tendons. Smith and Kaplan³⁵ have succinctly stated, “Virtually every structure at the base of the finger has been implicated as a deforming factor.” The pathogenetic factors that have been most often identified include an aberrant insertion of the lumbrical muscle and absence or adherence of the flexor digitorum superficialis tendon. McFarlane et al³⁶ have reported anomalous lumbrical muscles in 100% of cases. Kozin et al³¹ noted the same findings and have also elaborated on a classification system for camptodactyly based on the severity of the clinical findings and the reducibility of the PIP joint deformity. The first group includes those in which the PIP joint can undergo complete active extension when the MP joint hyperextension is passively corrected and blocked. In the second group, the PIP joint cannot achieve active full extension while the MP joint is blocked. The third group includes digits with irreducible PIP joints fixed at less than 30 degrees, and the fourth group includes fixed contractures of greater than 30 degrees.

Treatment for the disorder includes operative and nonoperative strategies. Most patients are treated nonoperatively, especially children. Nonoperative treatment includes home therapy and splinting. Home therapy should be performed by the parents or the patient two or three times per day, during which the PIP joint is stretched to correct its flexion deformity. Care must be taken NOT to apply force to the distal interphalangeal joint; otherwise, a secondary hyperextension deformity can result. The therapy should be supplemented with the use of a forearm-based splint worn a minimum of 8 hours each night, or, preferably, 23 hours a day. If the deformity persists after 6 to 12 months of splinting and is severe enough, exploration and correction of the lumbrical and/or flexor tendons is considered. The MP joint can be stabilized by any one of the variety of techniques previously described, including a palmar plate or a Zancolli lasso procedure. Irreducible PIP joints should be splinted. If the deformity is relatively asymptomatic and less than 30 degrees, then splinting is sufficient. If it is more than 30 degrees, then operative management should be considered.

With a wide variety of both causes and patients within each study, the treatment results have varied. Engber and Flatt³² reported that 80% of their cases showed progression of the deformity. Only 20% showed improvement with therapy. In their operative candidates, they report that only one third improved with operative treatment. Siegert et al³⁷ reported that only 18% of their patients with mild-to-moderate contractures (less than 60 degrees) showed improvement with surgery, whereas two thirds improved with nonoperative therapy. In general, most surgeons would not recommend operative intervention for a contracture of less than 30 degrees, and, for contractures of more than 30 degrees, they would consider operative intervention only if a trial of conservative measures had failed.³¹

Failure of Differentiation: Skeletal Tissue

Structural anomalies caused by abnormalities in osseous union occur at all levels of the upper extremity, from the elbow to the distal phalanges. They vary considerably in frequency and in their functional implications. The presence of an anomaly does not indicate that correction is necessary, and the need for surgical treatment is dictated by the functional implications of the anomaly. The anomalies range from irregularities in the shape of a phalanx to synostosis, in which the bones fail to differentiate and become fused into a single structure. Synostosis results from a failure of segmentation of the upper extremity.

Elbow Synostosis

Elbow synostosis can occur either between the humerus and the radius or between the humerus and the ulna. These anomalies are not common. Synostosis at the elbow level can have a profound impact on upper extremity function, with a fusion in extension preventing movement of the hand to the mouth and interfering with feeding, and a fusion in flexion preventing effective reach to the perineum for hygiene.³⁸ A congenital fusion between the humerus and radius can be associated with ulnar ray deficiencies, up to and including absence of the ulna. The synostosis occurs with the forearm and hand positioned in one of two positions: (1) with the elbow in moderate flexion, the radius pronated, and the hand positioned in ulnar deviation, or (2) with the humerus and radius positioned at a near-90-degree angle and the forearm pointing posteriorly. The fundamental principle in these anomalies is that surgery is indicated to improve positioning of the hand, where necessary. This can include rotational osteotomies and must be carefully planned to prevent neurovascular compromise.

Forearm Synostosis

Synostosis of the radius and ulna is usually proximal, but can occur more distally. The extent of the synostosis is variable, and hand function is often not affected.¹⁴ Indications for surgery are controversial and depend on the severity of the deformity and whether the synostosis is present bilaterally.³⁹ Cases with significant pronation deformity may benefit from derotational osteotomy of the forearm. Similar to treatment for elbow synostosis, prevention of neurovascular compromise is essential. The osteotomy is performed through the site of synostosis, and the hand position is corrected. Stabilization is obtained with pins or a plate and screw fixation. Although the derotational osteotomy positions the hand in a more favorable position, there is no establishment of motion of the forearm in the pronation-supination axis; this is something that the child and parents must understand fully before surgery.

Carpal Synostosis

Individual carpal bones separate from a common mass between weeks 4 and 8 of gestation. Incomplete cavitation of the common mass leads to persistent fusion. In contrast to elbow and forearm synostosis, carpal synostosis occurs quite frequently, with an incidence of 0.2% in whites and nearly 9.5% in some West African populations.³⁹ Lunotriquetral synostosis is the most common, followed by fusion between the capitate and hamate.^{14,40} Fusion can also occur between the proximal and distal rows of carpal bones. These fusions are frequently not evident until the second decade of life, when ossification of the carpal bones is complete. Although a congenital synostosis could lead to atypical load patterns within the wrist, most authors report that these anomalies are asymptomatic and result in no wrist dysfunction.⁴¹ Occasionally, a congenital fusion between carpal bones occurs as a synchondrosis with cartilaginous fusion but not as a true osseous fusion. Symptomatic synchondroses have been successfully treated by surgically creating osseous fusion at the affected sites.

Metacarpal Synostosis

Metacarpal synostosis is a rare anomaly that occurs most often between the fourth and fifth metacarpals but occasionally between the thumb and index metacarpal shaft and the central metacarpal shafts.^{14,42} Synostosis of the metacarpals most frequently is seen along the base, but it can extend more distally along the shaft toward the metacarpal head. This congenital anomaly is often associated with syndactyly, central polydactyly, Apert syndrome, symbrachydactyly, and thumb hypoplasia.⁴² When a synostosis occurs between the fourth and fifth metacarpal shafts, the fifth finger frequently can be angulated in an ulnar direction at the MP joint. Indications for surgical treatment depend on the ability to create functional digits after separation.

The fourth and fifth metacarpal fusions are treated by a longitudinal osteotomy extended transversely across the fifth metacarpal base, thereby preventing disruption of the carpometacarpal joint. The MP joint may require reefing and reconstruction of the radial collateral ligaments to correct the abducted posture of the fifth digit. Conjoined tendons need to be separated through the zone of synostosis. Usually, the fifth metacarpal is shortened, and this deficiency is lengthened at the time of osteotomy. The corrected axial metacarpal alignment is then maintained by the use of a block bone graft between the base of the fourth and fifth metacarpal shafts.⁴²

Symphalangism

In 1916 Cushing⁴³ referred to hereditary clinical stiffness of the joints as *sympchalangism*. The name has been extended to describe hereditary stiffness of the IP joints, although it is seldom applied to stiffness of the MP joints. Flatt and Wood⁴⁴ described a subdivision into three types: true symphalangism, symbrachydactyly, and symphalangism with associated anomaly. True symphalangism describes clinically stiff joints with phalanges of normal length. Symphalangism accounted for less than 1% of all congenital anomalies of the upper extremity in their series. It is frequently seen in association with brachydactyly.

Symphalangism is associated with the absence of flexion and extension creases in the affected joint. The absence of digital creases is a necessary but not sufficient criterion for the diagnosis of symphalangism. Stiffness to active and passive motion must also be present. The joint space may be detectable radiologically or clinically. The structural anomaly at the joint can range from partial bridging by cartilage to the complete absence of the joint with the obliteration by bone.

Surgical treatment of this disorder has been largely unrewarding despite multiple approaches, including the microvascular transfer of toe joints.⁴⁵ Deferring treatment until maturity and placing a silicone prosthetic joint have provided the most favorable results.⁴⁶

Clinodactyly

Clinodactyly is angular deviation in the radioulnar plane, whereas camptodactyly is angular deformity in the dorsopalmar plane of the hand. Clinodactyly of the hand typically involves radial deviation of the fifth digit at the level of the middle phalanx. This disorder can be inherited as an autosomal dominant trait with variable penetrance, and, when inherited in this manner, it usually occurs bilaterally.⁴⁷ Clinodactyly can also be inherited in association with multiple syndromes and chromosomal abnormalities.

Clinodactyly is caused by either a trapezoidal- or triangular-shaped bone of the phalanges. This usually exists at the level of the middle phalanx of the fifth digit, but it can involve other

Fig. 44-12 A, Clinodactyly caused by a longitudinally bracketed physis. B, Release of a longitudinally bracketed physis by resection of a portion of the epiphysis and growth plate. C, Release of a longitudinally bracketed physis by resection of a portion of the epiphysis and growth plate, which will be followed by the placement of an interposition fat graft. D, Correction of a longitudinally bracketed physis by a transverse osteotomy combined with either an opening or a closing wedge osteotomy.

metacarpals or phalanges and all rays of the hand, including the thumb. The trapezoidal-shaped bone can have a peculiar growth plate, known as a *longitudinally bracketed physis* or *delta phalanx*⁴⁸ (Fig. 44-12).

Clinodactyly usually does not cause functional impairment. Mild deviation (deviation less than 10 to 15 degrees) of the digits in the radioulnar plane may even be considered within the range of normal. When a deformity is more severe and leads to either a significant cosmetic deformity or functional difficulty, treatment can be beneficial. In these severe cases, splinting is ineffective, and a surgical osteotomy is often required. In cases with a delta phalanx (or longitudinally bracketed epiphysis), a surgical osteotomy can be performed through the abnormal physal plate. A segment of the epiphysis and growth plate is resected (bracket resection) (see Fig. 44-12, C), and an interposition graft of fat or other material is placed in the gap to prevent recurrence.⁵ Alternatively, the digit can be treated using an opening or closing wedge osteotomy⁵ (see Fig. 44-12, D). In cases amenable to bracket resection, surgery is effective at an early age but can be beneficial at any time before fusion of the physis. A formal opening or closing wedge osteotomy is technically challenging, particularly in a child's hand, and this should be considered in surgical planning. In patients who require a wedge osteotomy, surgery should be deferred until the child is older (8 to 12 years of age) and the bones large enough to allow effective control and surgery.

Triphalangeal Thumb

A triphalangeal thumb is often described as a *hypersegmentation abnormality* in which an additional phalanx develops during embryogenesis and differentiation. The additional phalanx may have the appearance of a triangular or delta phalanx, a rectangular phalanx, or a fully formed third phalanx⁴⁹ (Fig. 44-13). It is frequently associated with other anomalies, including polydactyly of the thumb, cleft feet, blood dyscrasias, and congenital heart disease. The Holt-Oram syndrome⁵⁰ is particularly common, and associated anomalies include atrial septal defect, ventricular septal defect, transposition of great vessels, and anomalous coronary arteries.⁵¹ The thumb anomaly itself has essentially three main problems: an abnormal phalanx, a first web space contracture, and hypoplasia of the thenar musculature.⁴⁹ Although function with a triphalangeal thumb may be adequate, the digit itself looks malformed, either from excessive length or from angular deviation caused by the third phalanx. The treatment for this disorder is surgical correction, and most surgeons recommend that it be completed during the first year of life.^{12,49} In surgical removal of

Fig. 44-13 Radiograph of a triphalangeal thumb.

the third phalanx, the periosteum and collateral ligaments both proximally and distally are preserved as much as possible. These are then sewn together, and the thumb is immobilized with a K-wire for 4 to 6 weeks. The deficiency of soft tissue in the first web space is corrected using one of the techniques described previously for syndactyly of the first web space. These include combinations of Z-plasties and the use of a dorsal hand rotation flap, depending on the degree of soft tissue needed. Thenar hypoplasia can be corrected at the initial surgery, or, if this is an equivocal finding, it can be observed and treated later as indicated. Options for treatment include various opponensplasties, such as a Huber transfer, an flexor digitorum superficialis transfer, or a palmaris longus transfer.

Congenital Tumorous Conditions

VASCULAR SYSTEM LESIONS

Vascular lesions of the upper extremity include hemangiomas and vascular malformations and share many similarities with their presentation in other regions of the body. Vascular tumors are the most common tumors of childhood.⁵² Almost invariably, these are benign lesions, with malignant vascular tumors being very rare and accounting for less than 2% of reported series.^{52,53} Mulliken and Young's text and classification system⁵⁴ provides a valuable framework for understanding this diverse spectrum of lesions.⁵⁵ Vascular malformations of the upper extremity are presented in detail in Chapters 11 and 13.

NERVOUS SYSTEM LESIONS

Neurofibroma or Neurofibromatosis

In children, neurofibromas may exist as isolated entities or as a part of the genetic disorder of neurofibromatosis type 1 (NF-1). NF-1 is common, with an estimated 100,000 cases in the United States alone. The clinical hallmark of the disorder is the development of multiple cutaneous and subcutaneous nodular tumors. The disease has a variable age of onset, a variable presentation,

Box 44-3 Clinical Diagnostic Criteria for Neurofibromatosis**Neurofibromatosis-1 (NF-1)**

Diagnostic criteria are met in an individual if two or more of the following are found:

- Café-au-lait spots (six or more larger than 5 mm in greatest dimension in prepubertal patients and larger than 15 mm in postpubertal patients)
- Two or more neurofibromas of any type or one plexiform neurofibroma
- Freckling in the axillary or inguinal region
- Optic glioma
- Two or more Lisch nodules (hamartomas of the iris)
- A distinctive osseous lesion such as sphenoid wing dysplasia or thinning of the long bone cortex with or without pseudarthrosis
- A first-degree relative (parent, sibling, or offspring) with NF-1 by the above criteria

Neurofibromatosis-2 (NF-2)

Diagnostic criteria are met if a patient has the following:

- Bilateral eighth nerve masses seen with appropriate imaging techniques
- A first-degree relative with NF-2 and either:
 - Unilateral eighth nerve mass or
 - Two or more of the following
 - Traumatic injury
 - Neurofibroma
 - Meningioma
 - Glioma
 - Schwannoma
 - Juvenile posterior subcapsular lenticular opacity

Data from 1987 National Institutes of Health Consensus Conference.

variability in clinical findings, and a variable but progressive course. Over the past 30 years, our understanding of neurofibromatosis has advanced significantly. Critical to this advance was a National Institutes of Health Consensus Statement in 1987^{56,57} that established the diagnostic criteria for peripheral neurofibromatosis, now known as *neurofibromatosis-1*, and central neurofibromatosis, now known as *neurofibromatosis-2* (NF-2) (Box 44-3). The prevalence of NF-1 is approximately 1 in 3000,⁵⁸ and the prevalence of NF-2 is approximately 1 in 60,000.⁵⁹ Both disorders are transmitted in an autosomal dominant fashion and associated with variable penetrance and expressivity. Families should be counseled that the chance of having an affected child is 50%. The gene for NF-1 has been localized to band 11.2 of the long arm of chromosome 17. The gene for NF-2 has been localized to the middle of the long arm of human chromosome 22, which is clearly distinct from the gene for NF-1.

Although the genes for both NF-1 and NF-2 have been identified and localized, the degree of variability is so high at these gene sites that the diagnosis of this disorder remains based on the clinical criteria.⁶⁰ The clinical presentation of NF-1 is most often heralded by the appearance of café-au-lait spots. These lesions are cutaneous hyperpigmented areas, typically 20 to 30 mm in diameter, and are the most common manifestation of NF-1, with more than six lesions found in 90% to 99% of all cases.^{61,62} Most children present with café-au-lait spots as the earliest manifestation of NF-1, but more than 80% will develop additional signs of the disorder. Axillary and

Fig. 44-14 An isolated neurofibroma of the distal radial sensory nerve in a patient with NF-1.

skin-fold freckling is seen in approximately 80% of all cases of NF-1.⁶¹ Freckles are generally extremely common, although not in areas that have not been exposed to the sun. Lisch nodules are pigmented, dome-shaped nodules on the surface of the iris.^{61,62} They appear later in life, usually by 10 years of age, and are present in nearly all NF-1 patients by 20 years of age. Lisch nodules are melanocytic hamartomas that are noteworthy for their diagnostic relevance, but they do not require treatment.

The NF-1 gene is a tumor suppressor gene. Optic pathway gliomas are the most common central nervous system tumors in patients with NF-1, occurring in approximately 15% of cases, and are histologically identified as low-grade pilocytic astrocytomas.^{61,62} NF-1 patients also have an increased incidence of brainstem gliomas and an apparent increase in the occurrence of benign and malignant astrocytomas, ependymomas, meningiomas, medulloblastomas, and malignant schwannomas. Skeletal abnormalities associated with NF-1 include sphenoid wing dysplasia, macrocephaly, scoliosis, and thinning of long bone cortex, frequently manifest as anterior tibial bowing.

Neurofibromas, the hallmark of the NF-1 disease, are nerve sheath tumors that may arise anywhere along a nerve sheath from the dorsal root ganglion to the terminal nerve branches⁶¹⁻⁶³ (Fig. 44-14). They are composed of Schwann cells, fibroblasts, mast cells, and perineural cells. The natural history of the disorder is characterized by steady growth of the neurofibroma, starting in childhood.⁶⁴ Surgical resection is the mainstay of treatment for enlarging or symptomatic tumors.

Neurofibromas occur in five main types: localized cutaneous neurofibromas, diffuse cutaneous neurofibromas, localized intraneural neurofibroma, plexiform neurofibromas, and massive soft tissue neurofibroma.⁶³ Localized cutaneous neurofibromas are the most common form. They are slow growing, and typically occur as multiple lesions that progressively increase in prominence throughout life. These lesions cause the pedunculated skin growths so frequently seen in NF-1. Diffuse cutaneous neurofibromas are plaquelike thickenings of the dermis and subcutaneous tissue that are most frequently found in the head and neck regions. They are nondestructive and grow along fibrous septa in children and young adults. They are generally soft and compressible to palpation. Localized and diffuse neurofibromas are generally absent at birth, but may appear as early as 5 years of age. Localized intraneural fibroma is the second most frequent type of neurofibroma and is the fusiform enlargement of a peripheral nerve. These are the most common type of neurofibroma of the upper extremity, accounting for 85% of cases.⁶⁵ Both spinal and cranial

nerves can be involved anywhere from the root to the smallest branches. Massive soft neurofibromas, previously known as *elephantiasis neurofibromatosa*, are rare in NF-1 and rare in the upper extremity. Plexiform neurofibromas are virtually unique to NF-1.⁶³ A plexiform neurofibroma outside NF-1 is extremely rare. They are composed of nerve sheath cells that proliferate along the length of a nerve, and are frequently associated with hypertrophy of the soft tissue and hyperpigmentation or hypertrichosis of the overlying skin. Their growth can cause destruction or compression of local tissue, leading to significant morbidity. Plexiforms occur in 16% to 40% of patients with NF-1. They are found on the trunk in 43% to 44% of patients, on the extremities in 15% to 38%, and on the head and neck in 18% to 42%.⁶³ In contrast to other neurofibromas, these plexiform lesions are thought to be congenital in origin and usually become evident by 2 years of age, perhaps only as an area of pigmentation or subtle soft tissue enlargement. Their growth is unpredictable and often occurs during early infancy and times of hormonal change such as preadolescence, adolescence, and pregnancy.

Malignant degeneration of peripheral nerve sheath tumors is more common than most think, occurring in up to 13% of patients with NF-1.⁶¹ Malignant peripheral nerve sheath tumors, which were formerly known as *neurosarcomas* or *malignant schwannomas*, arise from Schwann cells. Malignant soft tissue neoplasms occur approximately 34 times more frequently than in a control group and account for 9.4% of the deaths of patients with NF-1.^{61,63} More than 50% of patients with malignant nerve sheath tumors have NF-1.⁶³ Only the plexiform neurofibromas have a high propensity for malignant degeneration. Medium and large nerves, such as those involving the thigh, the buttock, the brachial plexus, and the paraspinal nerves, are usually involved. Pain appears to be the most reliable indicator of malignant degeneration. Prompt medical attention is warranted, and surgical biopsy is indicated. Once diagnosed, management consists of an aggressive attempt at total surgical resection. Metastases are common. Regardless of treatment, the 5-year survival rate of malignant peripheral nerve sheath tumors is estimated to be 16% to 52%.⁶³

Despite the possibility of malignant degeneration, surgical management of neurofibroma and neurofibromatosis in the child is usually based on balancing the benefit of tumor debulking/resection versus the potential loss of sensibility and/or motor function. Fundamental principles of surgical technique include the isolation of the peripheral nerve proximal and distal to the area involved; however, it is rarely possible to dissect through the neurofibroma and ensure the integrity of the nerve bundles. Debulking/resection is a surgical reduction in volume and may have consequences distal to the site of resection. The benefit of volume reduction and the potential improvement in pain must be weighed against the possible distal effects of major peripheral nerve surgery. In cases in which the continuity of nerves is interrupted, nerve grafting should be performed.

CONNECTIVE TISSUE LESIONS

Juvenile Aggressive Fibromatosis or Desmoid Tumor

Aggressive fibromatosis arises from connective tissue or muscle. The average age of onset of aggressive fibromatosis is the third decade of life, although it can develop as early as 1 month of age.⁶⁶ Approximately 5% of lesions are found in the hand. The lesion presents as a mass. Pain is seldom present. The tumor is benign but acts aggressively, with recurrence rates as high as 73%.⁶⁶ Recurrence with negative margins is low, but it is as high as 90% with positive margins and can occur within 3 months of excision.⁶⁶

Infantile Digital Fibromatosis or Reye Tumor

Infantile digital fibromatosis occurs as a single nodule or multiple lesions on the fingers and toes.⁶⁷ The lesions nearly always arise on the digit and typically present as a dome-shaped, smooth lesion on the extensor surface. In 80% of patients, the lesions are diagnosed during the first year of life.⁶⁸ Conservative treatment is indicated, but if functional problems or deformities arise, surgery is indicated. Surgical excision is the treatment of choice, but lesions recur in approximately 60% of patients, and this is the reason for the name *recurrent infantile digital fibroma*.⁶⁸ The lesions must be completely excised to prevent recurrence. Those that recur should be re-excised in a nonmutilating manner and grafted or covered with a pedicled flap, as indicated.

SKELETAL TISSUE LESIONS

Osteochondromatosis

Osteochondroma is the most common benign tumor of bone. It is generally asymptomatic, but it may be noticed because of its prominence or its impingement on other structures. It is extremely uncommon in the hand. The lesions are osseous bone growths with a hyaline cartilaginous cap. They can be associated with multiple hereditary exostoses, and these patients have a distinct skeletal problem—a lack of tubulation of bone.⁶⁹

Enchondromatosis

Enchondromas are the most common tumor of bone in the hand. They are benign cartilaginous lesions that typically arise in the proximal phalanx. In contrast, multiple enchondromatosis, or Ollier disease, is an uncommon nonhereditary skeletal disorder that is characterized by multiple prominent growths that cause obvious deformity and can impair function. The lesions usually continue to grow until the time of skeletal maturity and are generally not painful. They have a significant risk of malignant degeneration (approximately 30%), and any onset of pain, continued growth after maturity, or radiographic progression.^{70,71} Patients need to be followed clinically and radiographically for evidence of change that might suggest degeneration; a biopsy is performed if necessary.

Mafucci syndrome is characterized by multiple enchondromatosis, similar to Ollier disease. However, these patients also have multiple hemangiomas. The disorder is rare. The most common site of involvement is the hands. The radiographic appearance is identical to that of Ollier disease and has a similar potential for malignant degeneration. These patients must be followed clinically and radiographically.

Fibrous Dysplasia

Fibrous dysplasia is a benign disorder of bone that affects both the axial and the craniomaxillofacial skeleton. Hand involvement is rare. Fibrous dysplasia has not been classically considered a congenital disorder, because it is not usually evident at birth, but becomes clinically evident during late childhood or adolescence. Most importantly, it occurs sporadically, and genetic transmission has not been documented. Fibrous dysplasia has been traditionally divided into three main categories: (1) monostotic (or monocystic) fibrous dysplasia, (2) polyostotic fibrous dysplasia, and (3) the McCune-Albright syndrome. Most patients (70% to 80%) present with a single

area of bony involvement (monostotic or monocystic fibrous dysplasia); whereas others present with multiple sites of bone involvement (polyostotic fibrous dysplasia).⁷² Histologically, fibrous dysplasia is characterized by an expansile process with an accumulation of disconnected trabecular, poorly mineralized bone matrix mixed with normal lamellar bone. The histologic processes include marrow invasion, hyperresorption of bone with the development of lytic areas, and immature bone formation. The marrow cavity is filled with preosteoblastic cells. In the past decade, it was established that fibrous dysplasia results from a postfertilization somatic cell line mutation leading to a structural and functional change in the cellular transduction mechanism involving G-proteins.⁷²⁻⁷⁴ The G-protein is a membrane bound intracellular signaling mechanism that carries the message of extracellular hormone binding into the cell to create an effect. Hand lesions may remain asymptomatic. If fracture occurs from decreased bone strength, healing is usually uncomplicated in the hand.

CONCLUSION

Failure of differentiation of the hand includes a broad spectrum of disorders involving skin, connective tissue, muscle, nervous tissue, and vascular tissue. The disorders range from those that are very frequent (syndactyly, polydactyly, and camptodactyly) to those that are rare. Familiarity with the disorders in this group of anomalies is essential for providing care for these children. Each common disorder has several core principles.

KEY POINTS

Congenital Flexion Deformities of the Hand

- Assessment of a thumb flexion disorder requires evaluation of associated clinical findings and may include a variant of normal development, a congenital trigger thumb, or a congenital clasped thumb (supple or complex).
- Differentiation between these disorders is based on the joint that is flexed: IP joint flexion is probably a trigger thumb, whereas MP joint flexion can be a normal variant or a congenital clasped thumb.
- The initial management of the disorders with flexion at the MP joint is splinting, followed by reassessment every 2 to 3 months.

Syndactyly

- Syndactyly is one of the three most common congenital hand anomalies.
- A common classification system describes deformity as simple or complex and complete or incomplete.

- Surgery is typically performed during the first year of life.
- In hands with multiple digital involvement, only one side of a digit should be operated on in an operative procedure to prevent a vascular catastrophe.
- All syndactylous digits have a skin deficiency.
- Six fundamental tenets should be followed:
 1. All osseous and soft tissue between afflicted digits at phalangeal levels is completely separated.
 2. Nerves and the vascular supply are optimally preserved.
 3. An adequate web space is developed between the digits.
 4. Interdigitating flap coverage is ensured over the mid-lateral digit.
 5. Appropriate distal phalanges are developed.
 6. Full-thickness perforated grafts are used for areas of tissue deficiency.
- Effective immobilization of the upper extremity is essential to optimize graft adherence and clinical results.

Camptodactyly

- Camptodactyly is characterized by a flexion deformity of the affected digit in the dorsopalmar plane.
- This is one of the most common congenital anomalies.
- It is often associated with an absent lumbrical muscle.
- Splinting has limited effectiveness as treatment.
- Surgical correction is usually limited to digits with greater than 30 degrees of flexion.
- Surgical intervention has limited success.

Symphalangism

- Stiffness of the joints is associated with the absence of flexion and extension creases of the affected digits.
- Treatment is not usually beneficial.

Clinodactyly

- Clinodactyly is an angular deformity of the digit in the radioulnar axis.
- It is often caused by a malformed phalanx: a trapezoidal or a true delta phalanx.
- Often, this condition does not cause a functional impairment.
- Clinodactyly usually involves a mild deviation of 10 to 15 degrees from normal.

Continued

KEY POINTS (continued)

Triphalangeal Thumb

- Triphalangeal thumb is frequently associated with other congenital anomalies, especially cardiac.
- It involves the following separate problems: an abnormal phalanx, a constrained first web space, and hypoplasia of the thenar musculature.
- Many surgeons favor resection of the abnormal phalanx during the patient's first year of life.

Neurofibroma and Neurofibromatosis

- Neurofibromas exist in five main types.
- If a neurofibroma is diagnosed, the possibility of neurofibromatosis must be evaluated.
- If resection is required because of symptoms, the integrity of nerve tracts should be maintained, if possible, and those that are affected should be grafted.

The Apert Hand

Norma Timoney • Gregory H. Borschel • Ronald M. Zuker

Complex Surgical Case: Postoperative Outcome; Complex Surgical Case: Surgical Planning and Outline of Incision.

Apert syndrome is one of the craniosynostosis syndromes and is associated with symmetrical and severe bilateral syndactylies of the hands and feet (Fig. 45-1). The syndrome's many craniofacial anomalies include craniosynostosis, midface hypoplasia, and ocular hypertelorism with proptosis. Other malformations of the skin, the skeleton, the brain, and other internal organs occur with variable frequency. Apert¹ first described this syndrome in 1906.

Hand function in affected patients is limited by the presence of bilateral, symmetrical complex and complicated syndactylies with symphalangism, and, in some cases, metacarpal synostosis.

The entire upper limb may be affected. When synostosis involves the shoulder and elbow, the hand anomalies are usually less severe. Less than 5% of Apert children have congenital shoulder synostosis and rely on scapulothoracic movement.² However, most have a small glenoid fossa.

With growth, a discrepancy in size between an abnormally shaped humeral head and the glenoid fossa develops, although limitation of movement may not reveal itself fully until the patient has skeletal maturity. Shoulder range of motion tends to decline over time. For this reason, an orthopedic consultation is warranted. The elbow functions normally in most Apert patients, but 50% of patients show some radiologic anomalies.²

Fig. 45-1 A, Children with a typical Apert appearance. B, Typical Apert hands. C, Typical syndactyly of the toes.

GENETICS

The birth prevalence of Apert syndrome is thought to be approximately 1 per 65,000 live births (15.5 per 1 million live births). This constitutes approximately 4.5% of all craniosynostosis cases.³ Most cases occur as a result of new mutations—with a paternal age effect—and rare instances of inheritance are consistent with an autosomal dominant pattern.⁴ This condition is one of five craniosynostosis syndromes associated with allelic mutations of the fibroblast growth factor receptor 2 gene (*FGFR2*).

Nearly all known cases are accounted for by new mutations in the *FGFR2* gene. These mutations are distinct in position and nature.⁵ FGFRs are transmembrane receptor tyrosine kinase proteins that are involved in signaling pathways by interaction with fibroblast growth factors. They are strongly implicated in limb bud development anomalies.⁶

Two particular activating mutations are responsible for the changes seen. These cause amino acid substitutions: Ser 252 → Trp and Pro 253 → Arg (serine 252 to tryptophan and proline 253 to arginine).

Slaney et al⁷ analyzed the DNA of a group of patients and found a significant association between a particular mutation and the presence of either cleft palate (associated with a more severe craniofacial phenotype) or severity of syndactyly. The hand anomalies were most severe in those with the Pro 253 → Arg substitution, revealing a subtle but significant phenotype difference associated with each specific mutation.

ANATOMY

Anatomy of Abnormal Findings in the Apert Hand

The hands in Apert children are strikingly symmetrical. The deformity is complex, and the more common forms present with the following:

- Complex syndactyly of the index, middle, and ring fingers
- Simple syndactyly of the ring–little finger web
- Symphalangism of the index, middle, and ring fingers
- A short thumb with radial clinodactyly

Skeletal Abnormalities

Skeletal abnormalities include the following (Fig. 45-2):

- Capitohamate coalition at the carpal level
- Fourth to fifth finger metacarpal synostosis
- A bracketed longitudinal epiphysis on the radial border of the thumb proximal phalanx
- A broad and radially deviated thumb
- Stiff digits from symphalangism of the proximal and middle phalanges

Fig. 45-2 A, A left hand with fourth to fifth metacarpal synostosis and capitohamate coalition. B, Radial deviation of the thumb, resulting from a delta phalanx. C, Symphalangism with no proximal interphalangeal joint visible in the third, fourth, and fifth fingers.

Fig. 45-3 A, The palmar aponeurosis extends to the radial border of the thumb. B, The digital sheath is intact, with cruciate portions present only at areas of joint motion. C, The superficialis tendons arborize in a distal position and sometimes encircle the profundus tendon.

Soft Tissue Abnormalities

Large bands extend from the palmar aponeurosis to the radial border of the thumb. Strong interdigital bands connect the phalanges of the first web. The thenar muscles are always present, and the adductor pollicis and first dorsal interosseous muscles are often large when observed at the time of first web release.

A continuous digital retinacular sheath with cruciate portions is only present where joint movement is observed. The common digital neurovascular bundles tend to arborize in a distal position in each web. Bifurcations of the superficialis tendons are distally positioned within each digit.

Lumbricals are present, but with abnormal distal insertions into a variety of coalesced phalanges. They contribute to metacarpophalangeal flexion but not to interphalangeal extension⁸ (Fig. 45-3).

CLASSIFICATION

Syndactyly of the first web space occurs variably. Upton^{8,9} used this as a basis for classification of the Apert hand into three types. Type I has a spadelike appearance; type II is spoonlike or mittenlike; and type III is hoof or rosebud shaped. This classification is in general use. However, Van Heest et al¹⁰ described a classification based retrospectively on the radiographic features of the presenting anomalies of each hand and the surgical treatment provided.

Functional Implications

The severity of functional difficulty increases with classification type, beginning with type I. A lack of span in the first web prevents adequate grasp of larger objects, and syndactyly of the other digits limits a patient's ability to perform fine movements. Individual phalangeal joint movements are limited; therefore the digits are stiff, and finger flexion occurs at the level of the metacarpophalangeal joints and the distal interphalangeal joint of the little fingers. Radial deviation of the thumb impedes the pincer grip.

Cosmetic Implications

Even the mildest form of Apert syndrome hand has an unusual and abnormal appearance, compounded by the functional limitations of the condition. The hands are the next most visible area after the face and head and warrant consideration for treatment.

Descriptions of Classification Types

Type I

The type I hand, formerly described as *spade* or *obstetrician's hand*, is the least severe and the most common type (Fig. 45-4). The thumb-index web syndactyly is simple and relatively mild; thus

Fig. 45-4 A typical type I hand. **A** and **B**, The first web is shallow, and the fourth web has an incomplete soft tissue syndactyly. **C**, Outline of the anomaly.

Fig. 45-5 A type II hand. **A** and **B**, The first web has soft tissue syndactyly. **C**, An underlying complex bony fusion of the index, middle, and ring distal phalanges.

the first web space is shallow. A variable degree of radial clinodactyly may be present. The index, middle, and ring fingers are fused. A simple syndactyly occurs in the fourth web. The index, middle, and ring fingers have a bony fusion at the level of the distal interphalangeal joint, the distal middle phalanx, or the proximal terminal phalanx. Some degree of movement of the distal interphalangeal joint of the little finger is always present, unlike the other finger joints. Almost a full range of movement is possible at all of the metacarpophalangeal joints. The fused fingers form a flat configuration, and the thumb can oppose well.

Type II

The type II Apert hand was formerly described as having a spoonlike or mittenlike appearance (Fig. 45-5). Type II deformities are more severe than type I, because the thumb is joined to the rest of the fingers by a soft tissue syndactyly. However, there is no bony union, and the thumb and index finger have separate nails. The spoon-shaped appearance is caused by the complex fusion of the distal phalanges of the index, middle, and ring fingers and associated splaying of the proximal phalanges and metacarpals. The palm has a concave appearance. The syndactyly of the fourth web is complete, and there is a single conjoined nail for the index, middle, and ring fingers with some longitudinal ridges representing the individual distal phalanges underneath.

Type III

The type III hand was formerly described as hoof or rosebud shaped (Fig. 45-6). It is the most severe and the least common type. The first web has complex bony or cartilaginous syndactyly, the second and third webs have complex syndactyly, and all four (and often all five) digits have a single, conjoined nail. The thumb nail is small, and, in some cases, distinguishing the thumb from the index finger may be difficult. The syndactyly of the ring and little fingers is simple and

Fig. 45-6 A type III hand.

usually complete. A synostosis of the ring and little finger metacarpals may be present with associated limitation of mobility at the carpometacarpal joint level.

PREOPERATIVE EVALUATION

Evaluating the child in the newborn period and coordinating all surgical consultations and interventions are imperatives. A multidisciplinary team should be involved, including geneticists, pediatricians, anesthesiologists, physical therapists, social workers, and many others.¹¹

Airway problems and feeding difficulties are initial priorities. An upper limb intervention has to be coordinated with complex craniofacial procedures; a craniofacial coordinator usually assumes the clinical lead for planning surgical procedures.

The goals for hand function and the treatments that may be possible are determined. The hands are assessed during the early craniofacial assessment period. Radiographs of the hands are obtained at about 6 months of age to determine the extent of bony anomalies. CT scans with three-dimensional reconstruction may be helpful in type III patients because of the complexity of the anatomy. Routine laboratory tests are performed preoperatively to obtain hemoglobin and electrolyte levels.

TREATMENT OPTIONS

Nonoperative Treatment

Parents should be advised to maintain their child's upper limb passive range-of-joint motion beginning as early as possible. This complements later surgical intervention rather than substitutes for it. Hand therapy with appropriate thumb splints is part of the postoperative treatment phase.

Operative Treatment

Four broad categories of operative correction exist:

1. Digit separation by syndactyly release of all involved web spaces
2. Correction of clinodactyly
3. Release of metacarpal synostosis
4. Revision surgery

Traditionally, the border digits are separated first, particularly the thumb.

SURGICAL PLANNING

Operative Goals for the Hand

The ultimate goal of surgery is a hand that functions and appears as normal as possible. A hand with five digits and adequate web space formation is difficult to achieve. However, this should be the goal to allow optimal use.

Surgery should facilitate growth, and surgical scars should be placed to prevent growth limitation. A goal of surgical planning should be a minimum number of interventions, because these children undergo many procedures throughout childhood. Procedures should be planned and selected to require minimal revision. Surgery to both limbs and to a combination of web spaces can be performed with the patient under the same anesthetic to minimize the number of operations required. A further goal is to complete the hand surgery before patients are 5 to 6 years of age, when possible.

SURGICAL TECHNIQUE

Syndactyly Release

Type I Hand

For patients with type I hands, no treatment of the first web may be required if the web space is of adequate depth and full thumb mobility is possible. Bilateral release of the second and fourth web spaces may be carried out at 6 months of age. The syndactyly is simple but complete in most cases. The commissure is reconstructed using a dorsal flap (Fig. 45-7, A through C).

The dorsal flap needs to be a little longer than in cases of simple syndactyly because of the unusual thickness of the volar skin. Interlocking zigzag incisions are made along the fingers to prevent linear scars and to minimize the potential for scar contracture.^{12,13} Full-thickness skin grafts are taken from the lateral groin or lower abdomen to resurface the resultant defects. Careful selection of donor-site skin prevents the appearance of unwanted hair growth on the hand.

The middle and ring finger syndactyly is usually treated 6 months after release of the second and fourth webs. Particular problems occur during separation of the third web in Apert patients. Only rarely does adequate soft tissue remain over the bone and interphalangeal joints after this separation. Synostosis of the distal interphalangeal joints and fusion of the distal part of the middle phalanges are common. The proximal and middle phalanges are usually symphalangized, and separation of the digits results in a significant amount of bone exposure in the areas of bony fusion over the distal interphalangeal joints.

Some surgeons advocate the use of double-opposing triangular pulp flaps to re-create the nail folds¹⁴ or toe pulp grafts to cover the entire bony defect. This may result in rather pointed fingertips with some nail distortion. Zuker et al¹² stated that the use of pedicled distant flaps was a better option because it has less risk of scar contracture over the distal joint and subsequent deviation with growth. Pedicled groin flaps are individually designed to cover the defect and to

provide vascularized tissue over the bone, epiphyseal plate, and joint, and appropriately bulky tissue to reconstruct the pulp. The donor site can be closed primarily. In this situation a straight-line syndactyly release is performed in the distal portion of the fingers, with an osteotomy of the fused phalanges. A bilobed groin flap may be designed to cover adjacent finger defects. These areas are divided 10 days later, when the pedicle is divided (Fig. 45-7, *D* through *H*).

The aim of flap coverage is to provide sufficient soft tissue coverage to minimize both scar contracture over the epiphysis and subsequent problems with growth disturbance and deviation. The whole web is not covered with a flap, because this would necessitate a rather bulky, long flap with potential viability problems.

Bilateral pedicle flap surgery is inappropriate, because of the required immobilization and the older age of the child when the third web is treated. Thus some additional surgical procedures are necessary. Six months after the flap is inset, the remaining proximal syndactyly is divided using a dorsal flap technique to reconstruct the commissure, with interlocking zigzag incisions and full-thickness skin grafts to cover exposed areas. The long-term outcome in a type I case is shown in Fig. 45-7, *I* and *J*.

Type II Hand

In type II hands, bilateral release of the first web is the first priority where this is indicated, usually by 6 months of age. An incomplete soft tissue syndactyly can be released using a four-limb Z-plasty technique (Fig. 45-8).

Fig. 45-8 A, Incomplete soft tissue syndactyly of the first web. B, A four-limb Z-plasty to deepen the first web.

Fig. 45-9 This type II hand was reconstructed with a dorsal flap for the first web and grafts for the donor defect over the radial aspect of the index finger and the ulnar aspect of the thumb. A, Intraoperative view showing W-wire fixation. B, The two-year postoperative result.

The abnormal fascial bands that attach the thumb and index finger are released, along with the investing fascia over the first dorsal interosseous and adductor pollicis muscles. If the syndactyly is more severe, a dorsal first web space flap may be necessary. This can be done by taking a large dorsal flap that leaves a donor defect on the dorsum of the index finger (requiring a skin graft) or by using a dorsal V-Y advancement flap^{9,11} (Fig. 45-9).

Some surgeons have used tissue expansion successfully to provide adequate skin for first web reconstruction.¹⁵ A small expander with an externally placed port is inserted early in life, and reconstruction is performed before the child is 12 months of age. This technique is not widely favored, however. Distally based pedicled radial forearm fasciocutaneous flaps in this situation have been described but are generally reserved for the correction of secondary deformity in adult Apert patients.⁹

Bilateral fourth web release is performed during the same surgical episode as release of the first webs.

Release of the third webs can begin at 12 months of age. Initially, on one side, the distal part of the web is divided, and the deficient soft tissue over the bone and joint is reconstructed with a pedicled groin flap. The flap is divided at 10 days. The proximal web is deepened further at the pedicled flap reconstruction of the opposite side. The final web deepening is performed about 6 months later, when the child is 2 years of age. The second web may be released in the

Fig. 45-11 The long-term outcome in a severe type II hand. **A**, Volar view. **B**, Dorsal view.

opposite hand during the flap reconstruction. Long-term results in a type II case are shown in Figs. 45-10 and 45-11.

Type III Hand

Early drainage of paronychia infections may be necessary in a type III hand where pockets of macerated, compressed pulp tissue within the unified nail area have become infected. This may be needed early in the newborn period. Assessment of the bony anatomy can be difficult in these patients, and a preoperative CT scan with three-dimensional reconstruction is helpful.

Some surgeons advocate excision of the whole index ray at the first web reconstruction to ensure a better first web span. However, when this is done, the goal of a more normal hand, with four fingers and a thumb, cannot be achieved. It seems that the initial benefits for hand function are not great, and the long-term sequelae of metacarpal instability are difficult to manage.

Bilateral thumb-index separation is carried out when the patient is 6 months of age at the same time as separation of the ring–little finger web. The first web always has soft tissue deficiency, and a dorsal flap is used to reconstruct it. A proximally based flap from the base of the first to third webs is raised, preserving the dorsal branches of the radial nerve. Skin grafts

are necessary to cover the donor skin deficiency over the first dorsal interosseous muscle. The thumbnail is often small and difficult to delineate from that of the index finger.

Release of the second and third web space on opposite hands may begin at 12 months of age. Release of the third web is performed as described previously, with a combination of pedicled flaps in a distal position, web reconstruction with a dorsal flap, and full-thickness skin grafts to the proximal areas interspaced with interlocking zigzag flaps.

Clinodactyly Release

Thumb radial clinodactyly is usually corrected when a child is 3 to 5 years of age. The thumb is short, broad, and radially inclined because of the presence of a triangular proximal phalanx and a wide terminal phalanx. The deformity becomes more prominent with growth. A longitudinal epiphyseal bracket on the radial aspect of the proximal phalanx, which combines the proximal and distal joint surfaces, is responsible for the triangular shape of the phalanx and the radial deviation of the digit that occurs with growth. With growth and maturity the interphalangeal joint usually becomes fused. Before surgery, hand therapists assess the child's function, and, with the surgeon, decide whether the child's function is likely to be improved with an osteotomy. Many of these children may not need surgery for this functional (and aesthetic) issue.

An opening wedge osteotomy to improve length and correct angulation is the operation of choice for thumb clinodactyly.¹⁶ The surgeon approaches the area through a radial Z-plasty incision situated as distal as possible along the midaxial line. This allows some soft tissue elongation. Care is taken to preserve dorsal sensory nerves and veins. The interphalangeal joint is located by passive motion, and the attachment of the abductor pollicis brevis and radial collateral ligaments needs to be lifted to access the phalanx. The bracketed epiphysis is usually situated more to the ulnar side of the metacarpophalangeal joint and is difficult to access. Osteotomies on these small bones are challenging. The surgeon performs a transverse and distally positioned osteotomy, leaving the ulnar-side periosteum intact and removing a wedge of bone. This is rotated 180 degrees and inset into the osteotomy site (Fig. 45-12).

A bone graft is usually required, and different sources are available. Good-quality cortico-cancellous bone can be obtained from the iliac crest, but sufficient bone may be found at the site of division of the fourth and fifth metacarpal synostosis and can be obtained during the same surgical procedure.

Fig. 45-12 Osteotomy planning for correction of thumb radial clinodactyly.

The surgeon immobilizes the area with paired longitudinal K-wires. Soft tissue elongation is achieved through Z-plasty alone, although the addition of skin grafts may be necessary. The K-wires are removed after bony union has been confirmed, but further support with a splint is continued for 2 to 3 months.

Both the thumb and index finger may be effectively straightened with this type of procedure, which, in appropriate cases, can improve pulp-to-pulp pinch and grip strength. The index finger may also be radially inclined because of the presence of abnormal skeletal components. A radial longitudinal epiphyseal bracket of the proximal phalanx, which articulates with the distal phalanx, may be present, because of symphalangism of the proximal and middle phalanges. After division of the second web, and with growth, the deformity becomes visible. If a split epiphysis is present, the radial part does not contribute to the longitudinal growth of the phalanx. The middle phalangeal bone may be abnormal and triangular and a main factor contributing to abnormal growth of the digit. The use of an osteotomy and distraction of the proximal phalanx to correct thumb clinodactyly has been described as a successful technique in a small number of patients.¹⁷

Metacarpal Synostosis

Synostosis of the fourth and fifth metacarpals causes a flatter configuration of the hand, restricting movement of the fifth ray. Synostosis of this kind is present in two thirds of Apert patients.⁸ An osteotomy and excision of bone joining the two metacarpals can improve grip strength and span of the hand.

If division of synostosis is performed at the thumb clinodactyly correction, bone graft material may be available for the thumb opening wedge osteotomy. However, early correction of synostosis has not been successful; the procedure should not be performed in patients much younger than 5 years of age to prevent re-formation of the synostosis. Insertion of an intervening buffer material is required to prevent re-formation. Various synthetic and autologous materials have been used, and Upton⁹ advised using deepithelialized skin. Release of the dorsal capsule of the carpometacarpal joint and/or the ligament attachments provides mobility and rotation capabilities at this joint.

POSTOPERATIVE CARE

A secure dressing, usually including a plaster cast, is essential after complex surgery on the hand, particularly in children younger than 2 years of age. The dressing should extend above the elbow, with the elbow in a partly flexed position, if it is to remain in place for at least 10 days for skin graft protection.

When pedicled flaps are used, the hand and arm have to be immobilized to the chest wall for approximately 10 days. This is achieved ideally with a well-fitting and well-padded soft bandage rather than a plaster cast. Plaster casts in this situation can lead to pressure sores and skin irritation or laceration. Children appear to tolerate this remarkably well.

REVISION SURGERY

Although the aim is to allow these children to have four digits and a thumb on each hand by school age, further surgery is often required, especially for type III hands. This may be needed to improve appearance and function. The appearance of the hands is important. During the teenage years concerns about visible scars, hyperpigmented skin grafts, and broad nail folds may arise. Redeepening of interdigital web spaces, reduction of soft tissue bulk, and excision of hyperpig-

Fig. 45-13 Final outcome showing a range of ability to grasp small and large objects with thumb–index finger precision.

mented and hair-bearing skin grafts may be required. Z-plasty for scar contracture may be necessary. The appearance of the nail folds can be improved by strip excision of the nail folds and eponychial fold reconstruction. For functional improvement, an osteotomy to correct angulation or rotation may be necessary. Fearon¹⁸ advocated midphalangeal osteotomies of the four digits to improve thumb-to-finger pinch and grasp.

TREATMENT OUTCOMES AND COMPLICATIONS

Minor areas of skin graft loss and tiny areas of marginal flap necrosis can occur. Major complications are rare. With expert anesthesia care, respiratory problems are unusual. Major infection complications and partial and complete digit loss are rare, although families should always be warned about these possibilities. In general, patients and families are pleased with a four-fingered hand that functions remarkably well despite the bony and cartilaginous limitations. It should have an adequate first web space, sufficient soft tissue to prevent wound breakdown, and the ability to pinch and grasp (Fig. 45-13).

ALTERNATIVE SURGICAL TREATMENT MODALITIES

Apert¹ attributed some observed delay in these children's development to their musculoskeletal anomalies. This observation may have prompted the need for early intervention, combining the correction of both the craniofacial and upper limb anomalies. Upton⁹ described three essential concerns in the upper limb: (1) skeletal unions, (2) failure of complete joint segmentation, and (3) incomplete separation of the digital rays. Traditionally, digit separation gives priority to the separation of the border digits, particularly the thumb, as described previously.¹⁶

Chang et al¹⁷ reported a simplified traditional approach. In their series, syndactyly release was performed using local flaps and full-thickness skin grafts taken from the groin in all cases, without the need for distant flaps. They also carried out a thumb osteotomy in conjunction with syndactyly, using the ulna as a bone graft donor site. The digits were separated and the thumb clinodactyly corrected by 2 years 5 months of age. However, the authors did not attempt to create five-digit hands in the type III cases in this series.

Fearon¹⁸ adopted a rather different approach for separating all five digits in each of the four limbs in two operations. This approach produced a different philosophy of timing of intervention and technique. The first phase of Fearon's technique uses a straight-line skin incision release of each syndactyly. His technique does not give preference to the border digits, allowing separation of nonadjacent webs and preventing difficulties with vascularity of the digits. It does not attempt to cover exposed bone or joint in the distal half of the interdigital space with additional grafts or flaps. Instead, these areas are left to heal by secondary intention. However, the proximal web is reconstructed using a combination of volar and dorsal flaps and full-thickness skin grafts taken from the lower abdomen.

Fearon's second phase of treatment evolved as a result of functional difficulties with daily activities such as dressing. During the second phase the surgeon performs osteotomies of the phalanges midway between the metacarpophalangeal joint and the distal interphalangeal joint of each finger. An opening wedge is performed in each case, and the digits are angulated to allow pulp-to-pulp pinch with the thumb. Thumb clinodactyly correction with bone grafting is performed at the same stage.

Matsumoto et al¹⁹ described the correction of thumb angulation and length in two Apert cases using an external ball-jointed distraction device. An osteotomy of the proximal phalanx was initially performed. After a 1-day waiting period, early distraction followed by 1 mm of daily lengthening with alteration of the external angle achieved satisfactory alignment without the need for bone graft or interference with the epiphyses. Premature bony fusion at the osteotomy site occurred in the first of their Apert cases, prompting a change in protocol.

Fragale et al²⁰ studied in vitro osteoblast cultures taken from skull bone samples of clinical craniosynostosis cases, including one Apert case. The craniosynostotic osteoblasts showed a lower proliferation rate than that of controls. They suggested that unorthodox *FGFR2* activation may play an important part in this.

Traditionally, division of toe syndactyly is not routinely performed but may provide a significant psychological benefit rather than a functional one. Fearon¹⁸ advocated it for this reason.

In the last 5 years our group and others have begun offering simultaneous release of all web spaces to highly selected patients.^{21,22} We do not offer this approach routinely, but only after certain criteria have been met.

Conceivably, all patients with multiple, adjacent, web space syndactylies could undergo release in a single surgical stage, including those with Apert syndrome, provided the skin coverage and vascular supply to each ray are sufficient. We have used this approach in 14 hands thus far, and we have been impressed with the level of satisfaction the families have expressed. We think that, for certain families, this simultaneous release approach is a valuable alternative to a conventional, staged approach. The main benefit of a single-stage approach lies in the potential to combine multiple stages into fewer (ideally one) operations. This approach may be especially relevant for families of Apert syndrome children. Because of their combined craniofacial and limb anomalies, most of these children undergo more than 20 procedures, each requiring a general anesthesia, by the time they are skeletally mature. Not only does this large number of surgeries present a logistical challenge to families and surgeons, particularly for those traveling from far away, it also raises an emerging concern that repeated general anesthetics in young children may impair neurologic development. The psychological impact of enduring multiple sequential operations and rehabilitation protocols in complex syndromes should not be discounted.

The first step in determining which families would benefit from simultaneous release involves the input of the hand therapist. He or she must critically evaluate the ability of the family

to endure what may be a more arduous course of postoperative rehabilitation, stretching, splinting than may otherwise be necessary with a series of smaller operations. This decision is largely based on judgment and experience.

If the therapist and surgeon concur that the family can tolerate the rehabilitation, then arterial phase CT angiography is performed. We use a special protocol to reduce radiation exposure to very small levels roughly equivalent to those of a conventional chest radiograph. Sedation may be needed for the study, which can often be combined with a craniofacial CT as needed. We review the CT angiogram with our radiologist to determine whether each ray has at least one robust-appearing artery and simultaneously formulate an operative plan. The family should be informed that, although no cases of digital loss have been reported so far, such a loss may occur if vascularity is inadequate.

If we think that a child is a good candidate for simultaneous release, then we plan to release all webs during one anesthetic event. We use a two-team approach to minimize operating time. Cases of 10-digit syndactyly require more than 6 hours of total operating room time. We use a hand table on one side and a standard operating table on the other. Bilateral upper arm pneumatic tourniquets are used, and intravenous access is obtained with lower extremity lines. The entire lower abdomen is prepared and draped for full-thickness skin graft harvesting, which will leave a transverse scar from hip to hip in cases with all webs involved.

The design of the flaps incorporates dorsal quadrilateral flaps and straight-line releases, as with a conventional, staged release. The main difference is that comparatively more skin graft area may be needed if all webs are to be released. However, we have not found this to be a significant functional or aesthetic issue so far.

We generally release the border digits first, especially in type III cases. However, some surgeons prefer to release the first and third webs to mirror one of the more popular conventional approaches. We then sequentially release each web, examining the neurovascular bundles in each case. A CT angiogram accurately predicts the presence of arteries, but the test is not sensitive enough to detect very small arteries in some cases. In all cases we have treated thus far, every digit has had at least one major artery, and most have had two. Once the release is completed, we obtain templates of the defects, transfer them to the abdomen, and harvest full-thickness skin grafts. Usually, no undermining is needed to close this donor site, but cases that require a large amount of graft might require undermining of the abdominal skin to facilitate closure. We secure the grafts with 6-0 polylactic-co-glycolic acid (Vicryl Rapide) sutures and close the donor site with layered 4-0 and 5-0 polycaprolactone (Monocryl) sutures.

We used to use hard plaster dressings; however, in the last 5 years we have transitioned to a simpler soft “boxing glove” dressing. This type of dressing is commonly used in Australia and the United Kingdom for syndactyly and other congenital hand surgery but is not often used in North America. We place antibiotic ointment and a nonstick gauze dressing (Bactigras or an equivalent) in the webs to cover the grafts, followed by soft roll gauze (or an equivalent soft absorbent gauze) in the webs. The placement is easier when the fingers are held apart by temporary stay sutures (such as 4-0 silk sutures). We wrap the hand up to the wrist in the same soft roll gauze and clean the upper extremity to remove detergent and any other substance that can interfere with taping. Then, we wrap the hand with sticky tape. (We prefer Hypafix, because it is very sticky yet pliable.) Tape is applied from the level of the hand to nearly the axilla to ensure it remains secure for one week. In the clinic we generally reapply a new dressing 1 week postoperatively. Typically, the healing is adequate by 2 weeks to allow unrestricted motion. If healing is not sufficient, then a lighter dressing, applied in the clinic, may be needed for another week.

Outcomes

We have found that patients are satisfied and function is adequate (Fig. 45-14). Whether the functional and aesthetic outcomes of this approach are truly equivalent to those of conventional, staged surgery is unknown. As documented in our report,¹² we noted one episode of cellulitis requiring IV antibiotics, and one family had difficulty complying with the therapy regimen. One patient required a secondary release for a severe flexion contracture that could not be completely corrected at the initial operation. Overall, our data show a high level of satisfaction with this approach, although we have yet to benchmark this satisfaction level with that of a conventional approach. Nevertheless, the outcomes appear to be overall equivalent to those of a conventional, staged release.

KEY POINTS

- Apert syndrome is one of the craniosynostosis syndromes and is associated with symmetrical and severe bilateral syndactylies of the hands and feet.
- The hands in Apert children are strikingly symmetrical. The deformity is complex and has the following characteristics:
 - Complex syndactyly of the index, middle, and ring fingers
 - Simple syndactyly of the ring–little finger web
 - Symphalangism of the index, middle, and ring fingers
 - Short thumb with radial clinodactyly
- Surgical priorities include the following:
 - Digit separation by syndactyly release of all involved web spaces
 - Correction of clinodactyly
 - Release of metacarpal synostosis
 - Revision surgery

Polydactyly

John A. Girotto • Rajiv Sood

DEFINING THE PROBLEM

Polydactyly is the presence of more than five digits on one extremity. This encompasses many heterogeneous abnormalities, including partial and complete duplication of parts, occasionally with concomitant syndactyly. The word *polydactyly* is often used to describe supernumerary digits, whereas *duplication* usually refers to thumb anomalies. The appearance is easily noticed and difficult to conceal, leading to an immediate cosmetic concern for parents and an eventual cosmetic concern for patients. A rudimentary digit may interfere with the function of the primary digit, depending on the level of duplication, destabilizing the joint by separating its radial and ulnar attachments or by stiffening the joint irreparably. Many of these secondary abnormalities are more thoroughly discussed in other chapters.

In the United States, ulnar polydactyly is the most common congenital hand anomaly, with a prevalence of 1.5 to 1.7 per 1000 live births.¹ It is associated with many syndromes (Table 46-1) but often occurs sporadically.¹⁻⁴ Ulnar polydactyly is twice as common in males than females⁵ and 10 times more prevalent in blacks than in whites.^{6,7} Other polydactylies are much less common in general with a prevalence of 5.4 to 5.7 per 100,000 births.²

Several systems of categorization have been used in the past, including such nonspecific names as *preaxial* and *postaxial polydactyly*. Because of the surgical implications, many groups have suggested systems of categorization based on the bony anatomy. In an effort to form uniform terminology, the International Federation of Societies for Surgery of the Hand has adopted the modern Classification of Duplication (III)⁸ encompassing radial, central, and ulnar duplications (Box 46-1). Radial (or thumb) duplications are further classified most commonly by Wassel types I through VII (Fig. 46-1). This classification is based on the bony level of duplication. An incomplete bony separation of the distal phalanx constitutes type I, whereas a complete separation of the distal phalanx constitutes type II. Similarly, the proximal phalanx duplications are described

Table 46-1 Syndromes Associated With Polydactyly

Syndrome	Hand Findings	Systemic Findings
Ulnar Polydactyly		
Trisomy 13	Polydactyly	Microcephaly and mental/motor challenges Meningomyelocele Cleft palate Eye defects Urogenital defects Heart defects
Bardet-Biedl	Polydactyly, syndactyly	Heart defects Obesity Urogenital disease Mental/growth delay
Smith-Lemli-Opitz	Polydactyly, foot syndactyly	Microcephaly and mental challenges Malformation of the heart, urogenital tract, and gastrointestinal tract
Radial Polydactyly		
Fanconi anemia	Radial hand differences	Pancytopenia Short stature Eye problems Hearing problems Malformation of the heart, lungs, kidneys, and digestive tract
	Townes-Brocks	Imperforate anus Hearing problems and ear-shape malformations Malformations of the heart, kidneys, and genital tract
Holt-Oram	Thumb hypoplasia	Cardiac abnormalities

Radial (thumb)

Wassel types I-VII

Central

Often associated with syndactyly (complex)

Ulnar (fifth digit)

Types A, B

as types III and IV. Wassel type VII deformity, or triphalangism, is a separate entity and refers to an extra phalanx (rather than an extra digit). This phalanx can be rectangular or wedge shaped, and fully developed or hypoplastic, with implications about size, curvature, and related functional problems. Triphalangism with an additional duplicated thumb is most often seen in Wassel type IV (Fig. 46-2, *A*) and Wassel type VII duplications (Fig. 46-2, *B*). In 2008 the Rotterdam group⁹ expanded the thumb duplication classification to include triphalangism.

Fig. 46-1 The Wassel classification of thumb polydactyly.

Fig. 46-4 Ulnar polydactyly. **A**, This clinical presentation is not within the classification. **B**, A radiograph of the same patient.

As many pediatric hand surgeons have observed, and as Ezaki¹⁰ has described, thumb polydactyly does not mean that the thumb is really duplicated; it is more correct to describe it as split thumbs at certain levels (that is, Wassel types I through VI). Each one is smaller than the corresponding digit on the unaffected side. In some cases, creating one normal-sized digit by linking the two duplicated thumbs together might be imagined. The structural development problem is not only size related but affects all tissues. Thus the tendons, joints, ligaments, and other tissues distal to the duplication are not normal. Reduced range of motion and joint instability can be anticipated, and patients should be followed for these throughout the growth period.

Ulnar, or fifth finger, duplications are either a fully developed digit (type A) or a rudimentary appendage (type B) (Fig. 46-3). A classification system comprising three types has been described, in which type I correlates with a rudimentary appendage, type II includes duplication of the metacarpophalangeal joint, and type III includes duplication of the entire ray.⁶ Given the variability of expression, some presentations are not represented in standard classification schemes (Fig. 46-4).

Central duplications are rare and often involve syndactyly (failure of differentiation), overlapping their classification. Syndactyly is more thoroughly discussed in Chapter 44, and the classification is discussed in Chapter 41.

Epidemiology

The most significant advances concerning polydactyly involve factors that influence in utero development of fetal limbs. However, the embryologic causes of duplication have not been defined. Despite various systems of classification, treatment has focused on removal of one of the duplicated (rudimentary) parts. More recently, treatment has been recognized as reconstruction, not simply removal, of the affected digit. This includes concomitant joint and tendon rebalancing with removal of the duplicate digit.¹¹

Genetics

Limb development occurs during weeks 5 through 8 of gestation, with limb bud formation and the emergence of the polarizing region of the apical ectodermal ridge.¹² Polydactyly results from defective patterning of the anteroposterior axis of the developing limb. Several *HOX* genes encode critical transcription factors related to the development of synpolydactyly.¹³ Specifically, mutation of *HOXD13* is associated with limb synpolydactyly.^{14,15} The dHAND transcription factor plays a critical role in the anteroposterior orientation of the polarizing region of the apical ectodermal ridge.¹⁶⁻¹⁸ The *sonic hedgehog* (SHH) signal from the polarizing region of the limb bud may appear in an ectopic anterior location, giving rise to radial polydactylous duplications.^{12,19} Mirror anomalies have been experimentally created by moving the SHH signal to an anterior border location.^{12,18}

Transmission of polydactyly varies. A recent meta-analysis of the genetics literature identified 310 different disorders that include polydactyly at presentation and involve mutations in more than 90 separate genes.²⁰ All patterns of inheritance were represented (autosomal dominant, recessive, X-linked, and multimodal), but more than 109 syndromes had an unknown mode of inheritance.

A triphalangeal thumb (TPT) and its related polydactylous forms (that is, Wassel type IV, A and B, and type VII, A through D) seem to be inherited as an autosomal dominant trait. A number of syndromes associated with TPT are possible. A careful genetic evaluation should be considered before surgical intervention. In families with inherited but isolated radial polydactyly, a link to chromosome 7q36 has been identified that affects protein SHH regulation.

Alternatively, central polydactyly has a definite autosomal dominant inheritance pattern but with wide variation in its expression. This may include complex syndactyly, which in this situation is often referred to as *polysyndactyly* or *hidden polydactyly*.

Ulnar polydactyly has a definite inheritance pattern, but it is more complicated than that of central polydactyly. When ulnar polydactyly is an isolated malformation, the inheritance pattern is autosomal dominant. This is commonly seen in blacks with the type B form. However, penetrance is variable, making tracking a direct lineage difficult. Alternatively, when ulnar polydactyly is associated with other anomalies or, as seen in whites with the type A form, the inheritance pattern is autosomal recessive, a careful genetic evaluation should be considered.

PERTINENT NORMAL AND ABNORMAL ANATOMY

Functional Implications

Duplicated digits often have anomalous connections of collateral ligaments, leading to joint instability. This is corrected by surgically reattaching the affected collateral ligament to stabilize the joint. For thumb and small finger duplications, the abductor inserts on the lateralmost digital remnant, thus pulling it into further abduction and destabilizing the joint. In turn, this position influences the developing shape of the distal aspect of the first normal bone on which the duplication rests. The abductor insertion and the joint shape must be surgically corrected to centralize and stabilize the reconstructed digit. Duplications within the joint can limit motion, leading

to a stiff joint that persists even after reconstruction. Ultimately, the bulk and orientation of the duplicated parts may block thumb-finger opposition. Surgical intervention should begin early with duplications that clearly interfere with thumb opposition.⁵

Cosmetic Implications

Our hands are rarely concealed with clothing and are often the first thing seen by another person. The cascade of fingers is a pattern quickly recognized by parents and strangers. The cosmetic implications of extra or duplicated digits are undeniable. Infants quickly learn to function with whatever parts of the extremity they have present, but when they are with other children they may be scrutinized and ridiculed. Treatment, which may involve staged operations, is often planned to conclude by the time the child begins school.^{5,21}

PREOPERATIVE ASSESSMENT

History and Physical Examination

Because polydactyly has been associated with multiple genetic syndromes, a careful and thorough evaluation is warranted in even the simplest cases.^{3,4} A history of hand abnormalities in siblings or the parents may shed light on a familial predisposition. If an associated syndrome is suspected, genetic testing and pediatric consultation are warranted.

Evaluation and Workup

Careful observation of the motion and function of the affected hand/digits should help to determine opposability and supple motion of an affected joint. The development of the affected digit in relation to adjacent digits is noted, including excess or hypoplasia of these structures and of the other hand. The condition and size of the nail and the quantity of soft tissue available are noted for reconstruction. In a Wassel type IV duplication, the metacarpal is often broad (broader than the one on the normal side), and the proximal phalanx that will be preserved is typically narrow (narrower than the one on the normal side). This relationship should be pointed out to the family, because it will be a noticeable residual asymmetry (relative to the normal side) after surgical intervention. Joint alignment, lateral stability, and bony angulation need to be assessed preoperatively and addressed at the initial operation. Last, the tendinous insertions must be noted on the anomalous parts to plan balancing and reinsertion on the reconstructed digit that remains.

Laboratory and Imaging Diagnostics

At a minimum, AP and lateral radiographs are obtained despite the child's skeletal immaturity. These views demonstrate baseline anatomy for classification and may be a critical guide to eventual reconstruction. Although discrete bones may not be identifiable, widened gaps between visible bones can indicate the position of aberrant bone in the future.²² This is true for all radial and central duplications and ulnar type A duplications.

Isolated ulnar polydactyly, however, is often more benign, and radiographic evaluation in children with a type B presentation may not be required.

NONOPERATIVE AND OPERATIVE TREATMENT OPTIONS

Indications

Reasons not to intervene surgically in the presence of polydactyly are rare. In most cases the supernumerary digit or the duplicated digit poses a cosmetic problem (as in type B ulnar polydac-

tyly), a functional problem (as in types IV through VII radial polydactyly), or both and requires surgical extirpation with reconstruction. Type B ulnar polydactylies are often treated by ligation in the newborn nursery. Reviewing this less invasive approach, Mills et al²³ examined 231 hands with at least 2 years of follow-up and found only 7% underwent surgical revision after ligation in infancy.³ Although effective in most cases, this practice can be complicated by infection, vigorous hemorrhage, and a commonly reported ulnar nipplelike remnant with a painful or hypersensitive neuroma.²⁴

Contraindications

The only contraindications to surgical reconstruction are concomitant congenital abnormalities that preclude an anesthetic induction.

PREOPERATIVE PLANNING

Operative Treatment

Ulnar supernumerary digits (type B) require only excision with control of the digital artery and careful division of the digital nerve below the surface of the skin. They do not involve aberrant tendinous connections and rarely involve the bone or joints. The skin is closed primarily over the ligated neurovascular bundle to prevent a painful, superficial neuroma.²⁴

Other duplications—on either the radial or the ulnar side—may necessitate removing the duplicated segments or combining the duplicated parts to achieve the best functional and aesthetic result. This requires restoring joint balance and stability by reattaching collateral ligaments, reefing the joint capsule, or a bony osteotomy.

The guiding principle is restoration of the axial balance of the digit laterally, volarly, and dorsally. This usually involves addressing all of the tissues—skin, tendon, ligament, and bone/cartilage.

Timing

The timing of surgery has been somewhat arbitrary. Most authors recommend surgical reconstruction before the first birthday. In ulnar polydactyly, simple type B cases can be performed in the nursery or during the newborn period. The more complex type A cases with bony attachments can be treated at about 6 to 9 months of age. Similarly, most thumb duplications can be treated when the patient is just younger than 1 year of age. At this age, the structures are large enough to identify and adjust, the anesthetic risks are low, and fine hand prehensile function has not yet developed. Complications such as joint instability, axial deformity, and infections occur more frequently in older children.²⁵ Rarely, if unsure of which digit to remove, the surgeon should delay surgery until function and usage can be assessed. This may take additional time to clarify.

Patient Positioning and Marking

Similar to other pediatric hand cases, preparation includes the use of an arm board, a tourniquet, loupe magnification, and general anesthesia. Unlike adult patients, who usually care for themselves, very young children receive total care from a caregiver; thus surgeons can correct both hands simultaneously, if necessary. Zigzag incisions are used to prevent linear scars, which cause contracture and growth disturbance during development. Border racquet-handle incisions work well when possible. The thumb is often approached from the radial side to preserve the metacarpophalangeal ulnar collateral ligament. Most thumb duplications are asymmetrical, with the radial digit being smaller and often nonfunctional. In this case, the radial digit is clearly the one

to remove. Approaching this digit from the radial side allows access to the structures that require exposure and reconstruction (the radial collateral ligament, the extensor and flexor tendons, and the bone and joint), preserving the ulnar structures. Careful marking should maximize preservation of hearty soft tissue coverage. Excess tissue can be trimmed during closure.

SURGICAL TECHNIQUE

Ulnar Polydactyly

Ulnar supernumerary digits with only a rudimentary appendage (type B) should be excised through a racquet-handle incision around the base of the supernumerary digit. The neurovascular structures should not be divided prematurely. The skin is incised, and the artery and nerve immediately below are identified. With continued dissection, the branch point of the fifth ulnar digital nerve and the supernumerary bundle can be seen. Bipolar cautery is used to divide the artery and provide hemostasis. The nerve is sharply divided below the skin level, and great care is taken to not pull up an attached segment of the normal digital nerve during the division. This catastrophic error leads to ligation or division of the fifth finger's ulnar digital nerve, resulting in anesthesia of that side of the digit. After division, the supernumerary digit is removed, allowing primary closure of the skin²⁴ (see Fig. 46-4).

Treating a type A completely duplicated ulnar digit is more complex than treating a type B pedunculated stalk.²⁶ Similar to thumb duplications, these complete fingers may have muscular insertions from the hypothenar muscles and collateral polydactylous ligaments that must be addressed with reinsertion. Unlike the thumb, the fifth finger is not often used in opposition or stressed laterally, gripping objects. The remaining finger must be strong in flexion, with axial stability. If the duplication extends from the level of the proximal phalanx, the abductor may require preservation and reinsertion (Fig. 46-5). If the duplicate is more proximal, aberrant insertions of the flexor brevis or opponens may require subperiosteal elevation and connection to the remaining digit.

Fig. 46-5 Type A ulnar polydactyly at the level of the proximal phalanx. **A**, The preoperative appearance. **B**, A zigzag lateral incision to facilitate exposure of involved structures.

Central Polydactyly

Duplicates that extend from the central digits are quite variable, and it is difficult to generalize regarding their specific treatments.²⁶ An element of syndactyly obscures the anatomy of the duplicate part and identification of the dominant digit (Fig. 46-6). Similar to other syndactylies, a paucity of skin is present despite an overall excess of tissue. Incisions should be carefully designed to prevent straight-line scars that tether developing digits, and all usable skin should be saved for closure. Surgeons must evaluate duplicate tendinous units and insertions. As with all polydactyly treatment, basic tenets should be followed, specifically:

- Preservation of skin
- Alignment of bone and articular surfaces
- Rebalancing of tendons and muscles

When duplicated central digits are removed, as with other ray amputations, the space that remains must be narrowed by approximating the intermetacarpal ligaments.

Radial Polydactyly

The aim of surgical reconstruction is to obtain a stable, yet mobile thumb of adequate size and shape. Stability and size relate to strength, both for grip and pinch. Thumb mobility is largely dependent on the integrity of the carpometacarpal joint. This is often normal in Wassel types I to IV. The range of normal metacarpophalangeal joint motion is variable in all people, specifically in the degree of flexion. Loss of interphalangeal joint flexion impairs tip pinch to some degree, but children compensate effectively without appreciating any significant loss of function.

Wassel Types I and II

In most cases of Wassel type I and type II polydactyly, the ulnar digital component is larger and more functional and should therefore be preserved. Care is taken to ensure adequate tendon function and to restore the radial collateral ligament as the interphalangeal joint is repositioned. In general, it is easier to repair the collateral ligament after the joint has been aligned and maintained with a K-wire. Occasionally, these distal duplications can be symmetrical raising the question of which thumb to remove. Attempting to preserve attributes of each, Bilhaut²⁷ described a central wedge technique in which the collateral ligaments are saved and only the central

Fig. 46-6 Central polydactyl with a component of syndactyly.

Fig. 46-7 A Bilhaut-Cloquet procedure for symmetrical distal polydactyly. **A**, The preoperative plan. **B**, The postoperative result.

Fig. 46-8 A Wassel type II duplication. **A**, Fully formed distal phalanges. **B**, The radiographic appearance.

redundant tissue is removed (Fig. 46-7). Postoperative grooving of the nail and asymmetrical growth from epiphyseal misalignment plagues this approach.²⁸ Success with a Bilhaut-Cloquet procedure requires precise alignment of the nail matrices and the open epiphyses. This precision is complicated by the lack of gross landmarks confirming the alignment. Consequently, some see no utility for this approach, because the complications are too high. Type II duplications have a full distal phalanx and aberrant flexor/extensor tendon insertions that are often displaced laterally (Fig. 46-8). These must be combined or reattached during the combination procedure bringing their insertion and pull closer to the longitudinal axis of the new digit. Occasionally, the eccentric tendon insertion must be split, creating a Y-shaped insertion that provides a more symmetrical line of pull on the distal bone. Similarly, collateral ligaments need to be reattached if one duplicate is completely removed.

Wassel Types III and IV

The most common type of thumb duplication is Wassel type IV. The common approach to these duplications includes a zigzag incision with a racquet-shaped excision of the thumb to be ablated, which is most often the radial component. Specific problems with this type of duplication include

Fig. 46-9 Wassel type IV polydactyly. **A**, Asymmetrical duplication at the metacarpophalangeal joint. **B**, The radiographic appearance. **C**, A zigzag incision with a racquet-shaped excision. **D**, Care in tendinous and ligamentous alignment. **E**, Flap closure and K-wire fixation.

a potentially eccentric insertion of the flexor and extensor tendon apparatus, a wide metacarpal head, lax collateral ligaments, and insertion of the abductor pollicis brevis on the radial thumb. Retaining the ulnar digit is preferable to provide stability at the ulnar collateral ligament for thumb-index pinch. This digit is almost always the larger and more functional of the two. In the rare instance in which this is not so, the surgeon must very carefully reconstruct the ulnar collateral ligament to prevent joint instability. The surgeon can sacrifice joint mobility in favor of stability. The approach may be through a proximally based flap involving the digit to be ablated or through a racquet-type incision at the base of the digit to be ablated, with zigzag skin flap extensions proximally. The flexor and extensor tendons are assessed and their course and insertions centralized and balanced. This is imperative to allow normal motion of the centralized reconstructed digit. The abductor pollicis insertion is dissected off the radial thumb and the radial collateral ligament, maintaining it on a proximally based periosteal flap. It is reinserted on the radial aspect of the ulnar (remaining) proximal phalanx to form a new, secure muscle insertion. The dissection should not be too deep, because the cartilage may be elevated from the epiphysis, inducing future bone growth. After reinserting the tendon and collateral ligament, the surgeon checks the adjustment using a passive tenodesis and thumb-index opposition and secures it with a small axial K-wire to maintain its proper position (Fig. 46-9). If an angulation persists at the interphalangeal joint after correction at the metacarpophalangeal joint, then a closing wedge

Fig. 46-10 Late angulation from inadequate collateral ligament reconstruction.

osteotomy is required at the distal portion of the proximal phalanx. A bulky dressing and an above-elbow thumb spica-type cast are placed to protect the repair. In type IV polydactyly, the metacarpal head may be excessively wide, and it is tempting to shave off a portion to decrease its width. Although this maneuver actually helps in the ligamentous repositioning of the digit, it creates the potential for growth irregularities. Reduction of the growth plate on one side will reduce the longitudinal growth potential on that side. This may lead to an angular deformity toward the scarred side of the growth plate.

More proximal duplications may have a narrowed first web space that requires opening with a four-flap Z-plasty. Preserving the ulnar collateral ligament prevents late instability and deformity (Fig. 46-10).

Wassel Types V and VI

Although less common than type IV, Wassel type V and type VI duplications must be approached with the same fundamental principles in mind. The duplicated metacarpal has significant attachments from the opponens pollicis and first dorsal interosseous, which are asymmetrical by definition. This anatomy leads to a widened joint surface and nonaxial line of tension. The ulnar duplicated metacarpal lies within the first web space, thus narrowing its overall span.⁷ If symmetrical, excising the ulnar duplicate and reconstructing the ulnar collateral ligament effectively enlarges the first web space without an additional procedure. The extensor mechanism is a combination of extensor pollicis longus ulnarly and extensor pollicis brevis radially. Combining or rebalancing these insertions on the remaining thumb is essential to create an axial line of action. These insertions can be preserved on a small periosteal cuff removed from the excised digit for ease of transfer to the remaining digit.

Triphalangeal Thumb

A TPT can occur independently or as variants of Wassel type IV or VII (see Figs. 46-1 and 46-2). A TPT is often associated with syndromic changes and should prompt a thorough evaluation. An extra middle phalanx is always present with TPT. Early radiographs may not show the cartilaginous middle phalanx, and an apparently wide joint space may be the only clue to its presence. If a duplication is associated with the TPT, the same selection criteria apply regarding which digit will be ablated (that is, the smaller, less stable, less functional digit, which is usually the radial).

However, TPT is difficult to optimize, and this has led some to advocate extirpation of the TPT. Some have proposed transferring the duplicated biphalangeal thumb onto the metacarpal, thereby accepting a shorter digit for increased stability.²⁹

Some surgeons advocate fusing the extra phalanx to the distal or proximal phalanx. This maneuver improves stability and normalizes the joint sequence. An unstable delta phalanx may be best dealt with by excision. Skeletal immaturity makes the radiographic evaluation of this aberrant phalanx difficult, thus complicating the surgical decision-making and postoperative assessment. Multiple reconstructive techniques have been proposed, which in itself is a testament to the difficulty of this reconstruction.^{30,31} For hands with five digits, including a TPT, pollicization is often advised.³²

For all types of thumb duplication, surgeons must attempt to address all of the issues leading to imbalance in the initial operation. The skin, tendons, ligaments, joint surface, and bone should be corrected into axial alignment. The same principles of reconstruction apply, as discussed earlier in the chapter, including tendon balancing, adequate collateral ligament reconstruction, and correction of all angular deforming forces. The impact on the thenar muscle is varied and can be considerable. This muscle deficiency affects the ability of the retained thumb to oppose, regardless of reconstruction technique. Residual asymmetry will not correct itself with time, but will worsen with growth. This creates a curved or zigzag digit that is less functional than a balanced one.

Adjunctive Procedures

With the dual goal of maximizing function and cosmetic appearance, treatment of digital duplication often requires multiple, staged operations. This should be discussed early with parents to prepare them for the overall timeline of correction of this complex problem. The need for revisions to improve stiffness and alignment is common with ongoing development.^{21,22} These procedures include scar revision, corrective osteotomy, arthrodesis, centralization, and collateral ligament reconstruction. Appropriate growth and development should be allowed before initiating revision. However, most abnormalities will worsen, not improve, with time.

POSTOPERATIVE CARE

An ideal dressing is comfortable, immobilizing, and secure. Crafting a bulky dressing that will not slip off challenges even the most experienced surgeons. Incorporating an above-elbow cast often ensures some resistance to the child's attempts to remove it. A dressing change scheduled after 2 weeks with suture removal and reapplication of the splint or cast may require giving a short-acting general anesthetic. The K-wires stay in place for 4 to 6 weeks to allow adequate healing of the joint capsule, collateral ligaments, and osteotomies.²¹ Cast removal and therapy through spontaneous motion begins at 6 weeks. Follow-up evaluation of cosmesis, range of motion, and stability may begin at 3 months. Radiographs should be obtained at this time to assess bony union, bony alignment, and epiphyseal growth potential.

TREATMENT OUTCOMES AND COMPLICATIONS

The success of a congenital hand reconstruction can only be adequately assessed after growth is complete. All parents want their child to have an excellent cosmetic and functional correction of polydactyly. However, this level of restoration is the exception rather than the rule. Ulnar type B pedunculated supernumerary digits are often excised without residual consequence. Thoughtful reconstructive approaches for duplicated thumbs have documented complications ranging from 20% to 50%.^{11,28} Even a conceptually simple Bilhaut-Cloquet central wedge technique

often results in poor growth plate alignment, stiffness, and residual nail deformity.²⁸ Because the epiphyses remain open, minor surgical trauma leads to premature closure and angulated growth. Reoperative rates are high. Before the initial operation, extra time should be spent with parents to emphasize the cosmetic imperfections and the need for secondary functional surgery.

The complexity of thumb duplication and its associated reconstruction lead to equally complex postoperative problems. Often a scar contracture can be managed by simple Z-plasty. Inadequate web spaces can be managed using regional flaps or two- and four-flap Z-plasty. As mentioned previously, axial alignment and stability of the reconstructed digit are paramount. In general, angulation does not correct itself with growth and requires careful assessment of its cause. Tendon insertions or alignment may need precise rebalancing after development has revealed imbalance. Similarly, joint stiffness tends not to resolve, but is functionally better than lax instability at both the interphalangeal and the metacarpophalangeal joint. Instability may require collateral ligament tightening, at minimum, and occasionally arthrodesis.

FUTURE DIAGNOSTIC, ASSESSMENT, AND TREATMENT MODALITIES

Future progress in this field will revolve around research into the exact cause of polydactyly and the possibility of intrauterine fetal surgical correction. With a new understanding of causes and the role of genetics, our current classification scheme may need revision, and alternative treatment modalities will evolve.³²

KEY POINTS

- Possible genetic syndromes should be considered.
- Surgeons should observe how a child uses the hand.
- Three-view radiographs (AP, lateral, and oblique) should be obtained.
- All possible outcomes are discussed with the family, including a timeline of treatments.
- Operative treatment involves the following:
 - Skin is preserved for closure.
 - Tendon insertions are balanced.
 - Collateral ligaments are reattached.
 - Osteotomies are performed to reorient the articular surface.
 - Axial alignment and balance must be accurate.
 - A cast is placed postoperatively to prevent removal by the child.
- Residual deformity is assessed after development.
- Secondary corrections are anticipated and planned.

Congenital Hand Anomalies: Overgrowth

E. Patricia Egerszegi

ongenital overgrowth of a digit and part or all of the upper limb is a rather uncommon condition. It can involve single or multiple tissues, and it can be isolated or occur in conjunction with a syndrome. Some of the earliest reports date back to the first half of the nineteenth century.^{1,2} However, little true understanding of this condition was gained from the late 1800s to recent years, when genetic advances emerged.³⁻⁷ Overgrowth is the clinical manifestation of various unrelated pathologic processes with differing causes. This is a probable explanation for this lack of progress. Contributing further to the confusion, various forms of the condition have been given different names; these include nerve territory-oriented macrodactyly,⁸ club finger,⁹ congenital localized gigantism of the hand, partial gigantocheiry, giant fingers,¹⁰ megalodactyly, dactylomegaly, macrodystrophia lipomatosa, gigantomegaly, local gigantism,¹¹ and macrodystrophia lipomatosa progressive.^{12,13}

CLASSIFICATION

Despite the confusion, a number of authors have tried to classify overgrowth of the upper limb (Table 47-1):

- Temtamy and McKusick's classification¹⁴ is based on whether the anomaly is isolated or part of a syndrome.
- De Laurenzi's classification¹⁵ is dependent on the rate of growth.
 - Stable: The malformation is noticeably larger at birth but proportionately constant in growth with respect to the normal parts of the limb.
 - Progressive: Overgrowth appears at or before 2 to 3 years of age and increases progressively during the growth period at a rate greater than those of the unaffected digits.

Table 47-1 Commonly Used Classification Methods for Macroductyly

Authors	Based on	Particular Features
Temtamy and McKusick ^{14,16}	Isolated	True macroductyly: equivalent to Kelikian and Flatt's type I Pseudomacroductyly: bones uninvolved; soft tissue tumors or anomalies (for example, hemangioma, lipoma, or edema from constriction band syndrome)
	Syndromic	Including: Congenital partial gigantism with metacarpal and phalangeal involvement, subdivided into: (a) Segmental hypertrophy: disproportionately progressive growth of all involved tissues (b) Crossed hypertrophy: affecting different areas on both sides of the body (c) Hemihypertrophy: an incidence of 1/14,300 births ¹⁴ ; digits less severely affected ¹⁶ ; can be associated with Von Recklinghausen neurofibromatosis, Klippel-Trenaunay-Weber syndrome, or Kelikian and Flatt's type IV ¹⁶ ; hamartoma (for example, pigmented nevi, hemangioma) and congenital anomalies (for example, cardiac, polydactyly, or cryptorchidism) present in 20% to 30% of patients ¹⁶ ; association with various tumors (for example, renal, adrenal, brain) ¹⁷ Von Recklinghausen's neurofibromatosis: café-au-lait macules; axillary or inguinal freckling; iris Lisch nodules; characteristic osseous lesions; neurofibroma and other typical neural benign or malignant tumors ¹⁸ ; autosomal dominant inheritance ¹⁹ Ollier disease: multiple, skeletal long-bone enchondroma; most cases sporadic, but mild form can be autosomal dominant ²⁰ ; malignant transformation potential of approximately 30% ²¹ Maffucci syndrome: vascular anomalies and enchondroma; not hereditary, phleboliths in approximately 43%; malignant transformation in approximately 16% to 19% ^{14,20} ; risk of other malignancies (for example, ovarian carcinoma, brain glioma) ²² Klippel-Trenaunay-Weber syndrome: hemihypertrophy of a limb, venous dysplasia, and cutaneous vascular malformation; nonhereditary ²⁰ ; manifestations progress with age ²³ Congenital lymphedema: congenital lymphatic insufficiency; autosomal dominant Milroy disease ²⁴ ; can occur in some other syndromes (for example, Noonan, Turner) ²⁴
De Laurenzi ¹⁵	Stable rate of growth Progressive rate of growth of the involved digits	Present at birth Appearing at or before 2 to 3 years of age
Kelikian ⁸ Flatt ⁹	Tissue involvement and manifestation of the disease process	I: gigantism and lipofibromatosis II: gigantism and neurofibromatosis III: gigantism and digital hyperostosis IV: gigantism and hemihypertrophy

- Kelikian⁸ and Flatt⁹ classified according to the tissue involvement and manifestation of the disease process.
 - I: gigantism and lipofibromatosis
 - II: gigantism and neurofibromatosis
 - III: gigantism and digital hyperostosis
 - IV: gigantism and hemihypertrophy

Ongoing genetic research may eventually lead to the development of a new, improved classification system.

PATIENT CHARACTERISTICS

Macrodactyly is a rare congenital hand anomaly, accounting for approximately 0.9% of all congenital hand anomalies.⁹ According to some authors, the incidence is slightly higher in males than in females¹¹; others note a fairly equal sex distribution.⁹ Most cases are sporadic, with no family history of the condition.^{8,10,11,20} Some associated syndromes have a known inheritance pattern (for example, Von Recklinghausen neurofibromatosis, which has an autosomal dominant pattern^{16,19,20,25}); isolated macrodactyly has no known hereditary cause. Although most patients with this malformation have no other associated malformations, syndactyly occurs in 10% of cases^{8,9,26} (Fig. 47-1). Nevertheless, some syndromic forms of overgrowth have recently been shown to be associated with genetic abnormalities. These include the following^{3,7}:

- Proteus syndrome⁷ (associated with AKT1 mutation³)
- Fibroadipose overgrowth (FAO)³
- Hemihyperplasia multiple lipomatosis (HHML)³
- Congenital lipomatous overgrowth–vascular malformations–epidermal nevi–scoliosis/skeletal and spinal (CLOVES) syndrome³
- Megalencephaly–capillary malformation (MCAP) syndrome³

The last four syndromes listed are associated with PIK3CA mutations.³

Fig. 47-1 A patient with macrodactyly and syndactyly.

Fig. 47-2 A patient with macrodactyly of the right index and middle fingers and Proteus syndrome. **A**, At 2 months of age, other stigmata of Proteus syndrome are not yet evident. **B**, The patient is shown at 13 years of age after three operations to reduce growth and correct angulation; the clinodactyly has partially recurred. **C** and **D**, Other manifestations of Proteus syndrome are evident at 13 years of age, including a right arm lipoma that was first noticed at 3 years of age. A T1 MRI at the midforearm level shows increased subcutaneous fat in the right upper limb.

Macrodactyly may be one of the earliest presenting features of some syndromic anomalies (Fig. 47-2). Some pediatric tumors can cause enlargement of a digit and should not be confused with macrodactyly.²⁷

HAND CHARACTERISTICS

Approximately 90% to 95% of patients have unilateral hand involvement^{8,9,11,26} (Fig. 47-3). Of these, approximately 60% involve the right hand, although some authors report an equal frequency and others note left-sided predominance.^{3,28} Multiple digits are two to three times more frequently affected than a single one.^{9,11,26,29} In multiple-digit macrodactyly, the involved digits are always adjacent,¹¹ and two digits are more commonly affected than three.^{26,29} When four or more digits are involved, hemihypertrophy is often present and should be evaluated.²⁸ The most commonly involved digit is the index finger (33% to 37%), followed in decreasing order by the middle finger (30%), the thumb (16% to 18%), the ring finger (12% to 14%), and the little finger

Fig. 47-3 A case involving a single digit. **A**, Single-digit macrodactyly of the left index finger. **B**, A PA radiograph of the left hand. Soft tissue volume is increased on the radial side of the digit.

Fig. 47-4 Progression of angular deviation of middle finger macrodactyly. The patient is shown **A**, at 2 months of age and **B**, at 7 years of age.

(3% to 7%).^{11,26} The most typical two-finger combinations are the index-middle and thumb-index, and the least common is the ring-little.^{11,26,29}

Macrodactyly can be limited to a digit or digits, or it can extend proximally various distances along the limb.^{10,11} The enlargement is more pronounced in the distal digit than more proximally.^{9,10,25,30}

The finger is not only longer but also wider than the normal digits.^{25,30} A degree of angular digital deviation in the coronal plane can occur, which can be progressive, forming a curvature (Fig. 47-4). Some authors have reported that the radial finger or fingers deviate ulnarly,^{11,16,28} and others have noted radial deviation.²⁵ The ulnar digits are also noted to deviate radially.^{25,28} Ogino¹¹ specified that the ring finger can deviate in either direction depending on whether the median or ulnar nerve is involved. However, when adjacent fingers are affected, they tend to diverge, according to some authors,^{10,25,28} and converge according to others.⁹ The affected thumb commonly assumes a hyperextended and abducted posture.^{9,16,25} Because the palmar aspect tends to be more severely involved than the dorsal surface,^{25,30} dorsal deviation can occur^{9,16} and can even be pro-

Fig. 47-5 Limited flexion of macrodactylous index and middle finger distal interphalangeal joints.

gressive. The joints often have limited flexion,^{25,30} particularly the distal interphalangeal joint,^{11,30} and this can progress with growth (Fig. 47-5), resulting in functional deterioration.^{9,31} Although longitudinal growth tends to stop with epiphyseal closure, in some cases transverse growth¹⁶ or the soft tissues may continue to increase.³² Pure nerve impairment is uncommon; however, compression neuropathy such as carpal tunnel syndrome can occur and necessitate decompression.^{9,11,33-36}

CAUSE AND PATHOLOGY

Although the exact cause of most types of macrodactyly is unknown, neural,^{9,30,31,37} vascular,³⁷ humoral,^{37,38} genetic,^{3-6,39} and a combination of genetic and environmental factors²⁹ have been proposed as possible causes of this anomaly.

Although some have discussed a relationship between macrodactyly and Von Recklinghausen neurofibromatosis, several authors agree that there are more differences than similarities.^{8,10,11} Many cases of macrodactyly are associated with enlarged nerves in the affected area.^{9-11,30,33,40} This has led to the term *nerve territory-oriented macrodactyly*.⁸ Some have interpreted this association to imply that the nerve is the cause of the disorder,^{9,25,30} because certain nerve disorders are known to affect growth (for example, brachial plexus injury results in decreased limb growth). Nevertheless, it is entirely possible that whatever causes enlargement of the affected structures also affects the nerves.³⁴ Nerve resection does not diminish subsequent growth. This supports the hypothesis that nerve enlargement is unlikely to be the only factor in the overgrowth.¹¹ It has been suggested that molecular biology or genetic studies for somatic mutations may eventually lead to a better understanding of the condition and its causative factors.^{38,41} Recent advances in genetic research have provided evidence that some forms of overgrowth may be related to anomalies at the genetic level, such as pleiotrophin upregulation⁴; mutation of PIK3CA^{3,4}; a gain-of-function mutation of the natriuretic peptide receptor 2 gene, causing excessive production of cGMP^{5,39}; and mutation of AKT1.³ Evidence exists that certain forms of overgrowth are limited to the somatic cell, and that they can arise from the same genetic foundations as some generalized mosaic overgrowth syndromes.⁶ These findings beg the question of whether timing and location of the genetic event may be factors explaining the difference between certain generalized and localized phenotypes.^{3,6}

The pathologic findings seen in macrodactyly include thickening of the skin with decreased sweat gland density.⁴² Increased subcutaneous fat with fibrosis,⁴² similar to that in adults, is found

Fig. 47-6 An enlarged median nerve extending proximally into the carpal tunnel of the right hand in a patient with macrodactyly.

with large, darker, firmly fixed lobules.²⁹ The tendons are generally not involved,²⁹ although they may be increased in size,¹⁰ with a thickened tendon sheath.²⁵ The arteries are enlarged,⁴³ particularly because of increased luminal caliber,¹¹ and, according to Flatt,⁹ during growth may not always keep up with tissue requirements, resulting in vascular insufficiency. The bone tends to be enlarged in all directions, with a widened medullary canal^{9,16,44} and thickened,^{25,44} fibrotic periosteum.^{37,44,45} Bone age is advanced in the involved regions as evidenced by an earlier appearance of the epiphyseal secondary calcification centers.^{10,11} The digital nerves, which are enlarged in width and length, are difficult to separate from the surrounding subcutaneous tissue and can have a tortuous course.^{10,25} Involvement often extends proximally into the hand and beyond^{9,11,16} (Fig. 47-6). There is an increase in fibrous and fatty tissue around the nerve.^{29,44} Some authors have also described thinning or degenerative changes of the myelin, which they interpret as effects of compression.^{30,46}

In the specific case of macrodactyly associated with hyperostosis, osteocartilaginous masses are present around the joints,^{11,25} and nerves may not be enlarged^{9,10,25} or may be infiltrated with fibrofatty tissue.¹⁶ This may therefore be an unrelated entity. Nevertheless, the involved area seems to follow a neural territory.⁹

PATIENT ASSESSMENT

Once a tumor^{27,47} diagnosis has been excluded—by history, examination, investigation, and, when indicated, biopsy—it is important to establish if the patient's macrodactyly is isolated or part of a syndrome. Macrodactyly that is part of a syndrome may require consultation with and treatment from other specialists or an interdisciplinary clinic. Symptoms of compression neuropathy should be sought in patients with significant palmar or proximal involvement, particularly in those old enough to collaborate for a reliable evaluation. Otherwise, patients are assessed for signs of this problem, because significant compression may begin at an early age and require decompression. EMG and nerve conduction studies can be helpful. Evaluation by an occupational therapist can aid in assessing function, identifying deterioration, and establishing the best treatment plan.

Fig. 47-7 Comparative hand radiographs in a patient with progressive macrodactyly of the right index and long fingers. **A**, Left and right hand scanographs at 16 months of age. **B**, Left and right hand radiographs at 5½ years of age. **C**, The hand appearance 3½ years after epiphysiodesis, with some recurrence of middle finger angular deviation.

Sequential comparative radiographs of the normal and involved hands and/or limbs help to determine whether the condition is static or progressive. These may include, if indicated, scanographs to assess for a limb length discrepancy (Fig. 47-7). Radiographs also are used for measuring the degree of coronal or dorsopalmar deviation and the exact sites contributing to the angulation. In some cases, a psychological evaluation and follow-up support may be useful in deciding the best treatment plan.

TREATMENT OPTIONS

There is no useful nonsurgical treatment of macrodactyly. Epiphyseal plate arrest through microangiography and embolization by ultraspecialized interventional radiologists may one day become a reality. However, this technique's use is limited to the treatment of larger bones, such as the ulna or radius (J. Dubois, personal communication, 2005). Although surgical treatment

of macrodactyly has no formal contraindications, short of life-threatening conditions, surgical treatment is controversial in some cases. These include more subtle forms with no functional impairment of the hand and patients who do not wish to have surgery.

In most cases, surgery must be tailored to each patient's needs, deformity, functional problems, and wishes. Staged surgery is often necessary⁴⁸ and long-term follow-up required.

PREOPERATIVE PLANNING

Historically, surgical treatment is subdivided into four general categories:

1. Early attempts at inhibition of further overgrowth
2. Intermediate-period longitudinal growth arrest
3. Early- to late-period debulking procedures in length and/or width
4. Other corrective procedures, including nerve decompression, correction of angulation deformities, or even amputation

The last category of corrective procedures can be undertaken at any time but is usually reserved for the intermediate and late periods and is not discussed in this chapter.

Surgical Plan

The choice of procedure depends at least in part on these factors:

- The patient's age at presentation
- Whether the malformation is static or progressive
- The severity of the macrodactyly
- Whether the digit has attained adult size
- Whether the curvature is significant
- The range of motion at each joint
- Whether multiple digits are involved

In my experience, and most surgeons agree, nerve stripping or excision does not slow the growth of a digit, even in young patients.^{9,49} However, nerve excision can be useful during otherwise planned debulking procedures, and, if undertaken bilaterally in a specific digit, at least one should be reconstructed with a nerve graft.¹¹ Because vascularization in these fingers is frequently precarious,⁹ ideally both or at least one digital artery should be preserved during nerve excision. If both sides of a finger require treatment, 2 to 6 months between procedures is suggested (depending on the author and technique).^{9,10,16,28,49-51} This may decrease the likelihood of vascular compromise.

To prevent longitudinal overgrowth of a finger if the growth plates are still open and the digit has grown to adult length, epiphysiodesis is indicated at the involved levels (usually all phalanges, possibly including the metacarpal). Angulation deformities can be corrected simultaneously. The incisions used should not interfere with further planned surgery.

Many previously described combination techniques for digit reduction correct longitudinal bony and soft tissue overgrowth. However, they generally address only soft tissue reduction in width. When treated using these techniques, grossly enlarged digits that are longer than adult size are shortened but often remain disproportionately wide. Although only a case report, the technique reported by Bertelli et al⁵⁰ shows promise, because it addresses both bony and soft tissue width and length. The technique includes a first operation involving resection of the ulnar thirds of the phalanges, detachment and reinsertion of the proximal interphalangeal joint collateral ligament, resection and fusion of the distal interphalangeal joint, removal of the ulnar soft tissues, including the neurovascular pedicle on the same side, and excision of the distal third of

Fig. 47-8 Amputation of a macrodactylous digit. **A**, This patient had an epiphysiodesis of the phalanges and soft tissue debulking of the middle finger of the left hand at 28 months of age. The patient is shown 3 years postoperatively. **B**, The middle finger was amputated when the patient was 5½ years of age. An epiphysiodesis combined with closing wedge osteotomies of the phalanges with soft tissue debulking of the ring finger was completed at 9 years of age. The patient is shown at 12 years of age.

the nail bed. Six months later, debulking is undertaken on the radial side, preserving the radial neurovascular pedicle. Although the result is impressive, the technique's worth needs to be confirmed in a greater number of patients.

Finally, for some grossly enlarged digits that obstruct function, amputation may be the best treatment option (Fig. 47-8).

Positioning and Marking

The patient is placed in a supine position, with the involved limb abducted and resting on a hand table. In very small patients, the head and shoulder can rest on the most proximal part of a sufficiently wide hand table. The rest of the body is positioned slightly obliquely away from the hand table toward the opposite-side foot of the main operating room table, because this allows the hand to extend farther onto the hand table, facilitating the surgeon's approach to the hand (Fig. 47-9). A tourniquet is applied and used intraoperatively (inflated to 200 mm Hg or less in younger children and at 250 mm Hg or less in older, healthy, normotensive children).^{52,53} The tourniquet is deflated for at least 15 minutes⁵³ after 1½ to 2 hours of inflation, and then it is reinflated.^{52,53} However, according to Crenshaw,⁵² it is less traumatizing to leave the tourniquet on for 2 hours or even a few minutes longer, then deflate and not reinflate it, than to deflate for 10 minutes and reinflate for the necessary additional time. Markings are made according to the technique planned (as described later in the chapter), and the patient is prepared and draped as usual. Prophylactic antibiotic agents are generally not given unless specifically indicated (for example, for multiple episodes of ingrown nail or prolonged surgery).

Fig. 47-9 Positioning a small child for hand surgery to allow the hand to lie far enough distally on the hand table to facilitate the surgeon's work. The head lies partly on the hand table and the body obliquely on the operating room table. The shoulder should not be abducted much beyond 90 degrees, and the head should not be completely turned to the opposite side to prevent traction on the brachial plexus.

SURGICAL TECHNIQUE

Early Inhibition of Further Overgrowth

Some authors have claimed that complete or partial digital nerve resection or stripping of its branches can prevent digital overgrowth.^{30,32} In my experience, and it is now generally agreed, this does not slow or stop growth.^{9,49} Nevertheless, if considered in conjunction with a debulking procedure, for example, it should be performed early enough to allow some reinnervation after nerve excision.¹¹ Nerve procedures may include excision of the hypertrophied part of the nerve and reanastomosis^{8,10,11}; nerve excision, with or without the skin it innervates^{11,16,49} (if both digital nerves are excised, reconstruction of one using a nerve graft is recommended¹¹); or longitudinal partial median nerve resection.⁵⁴ This last technique may be difficult or impossible if the nerve fascicles are torturous. Efforts must be made to keep the digital arteries intact⁴⁹ to minimize the chance of vascular compromise. The incisions are usually made according to the debulking procedure performed and the future planned surgery. If both sides of a finger require treatment, a period of 2 to 6 months between procedures (depending on both the author and the technique) is suggested.^{9,10,16,28,49-51}

Intermediate-Period Longitudinal Growth Arrest

Most authors agree that longitudinal growth should be arrested when the digit is the same length as the corresponding digit in the parent of the same sex. According to Ogino,¹¹ surgery is usually performed when patients are about 10 years of age. In larger bones (for example, the radius

and ulna), the use of intraarterial embolization of the growth plate may be possible (J. Dubois, personal communication, 2005). However, in small bones, such as those in the hand, such techniques have not been used for fear of compromising the distal circulation of the digit. Surgical epiphysiodesis is therefore the mainstay of longitudinal growth arrest. Various methods have been described to stop longitudinal bone growth, including cauterization,⁵¹ high-speed burring,⁵¹ surgical curettage,^{51,55} and surgical excision.⁵⁵ Although stapling has been attempted, it has proven too difficult to position the small staples across the epiphyseal plate.^{9,56} Angular deformity sometimes occurs after epiphyseal arrest (Fig. 47-10), and may require surgical treatment with a wedge osteotomy.⁴³ If a degree of deviation is present in any plane when epiphysiodesis is undertaken, a wedge osteotomy can be performed simultaneously^{25,49} (Fig. 47-11). Some have attempted hemiepiphysiodesis on the convex side of the finger, but results have been less reliable than those obtained with a corrective osteotomy.²⁵

Fig. 47-10 Recurrence of angular deviation after a closing wedge osteotomy followed by epiphysiodesis of the macrodactylous middle finger phalanges. **A**, The hand appearance before bony intervention. **B**, The hand appearance 2½ months after an epiphysiodesis of the index and middle finger phalanges and closing wedge osteotomies of the middle finger proximal and middle phalanges. **C**, The hand is shown 3½ years after an epiphysiodesis, with some recurrence of middle finger angular deviation.

Fig. 47-11 A combination of epiphysiodesis and closing wedge osteotomies to correct angulation and arrest longitudinal growth. **A**, A radiograph obtained 1 year after closing wedge osteotomies at the junction of the middle and distal thirds of both the proximal and middle phalanges of the middle finger and before an epiphysiodesis. **B**, A radiograph obtained 16 months after an epiphysiodesis of all phalanges of the index and middle fingers, including closing wedge osteotomies at the level of the epiphysiodesis for the proximal phalanx of the index finger and both proximal and distal phalanges of the middle finger.

Although surgeons should take into account future surgeries when planning cutaneous incisions, they are often made in the midlateral line on the convex side of the digit.

Early- to Late-Period Debulking Procedures

Early- to late-period debulking procedures include those aimed at the soft tissues, the bone, or both. Soft tissue procedures can be undertaken at any time and involve variable and often sequential excisions of skin and subcutaneous tissue, including or excluding the digital nerve or its branches. Most surgeons recommend debulking half the circumference at a time, with an interval of 2 to 6 months between procedures^{9,10,16,28,49-51}; however, a palmar pedicled flap and a dorsal island flap have been described, one based on the radial and the other on the ulnar neurovascular digital pedicle.⁵⁸ It is important to preserve the digital arteries, particularly in cases in which debulking is planned bilaterally.⁴⁹ Most authors describe using a midlateral incision.^{9,25,28,49} Some authors have mentioned a Brunner incision,^{9,16,25,50} but Flatt⁹ has reported that the resulting scars are more frequently hypertrophic.

Bony reduction procedures tend to be reserved for the intermediate and late periods. They include reductions in length using resection osteotomies to shorten bones,^{11,16,25} which can be combined with a correction of angular deviation^{9,16,25} and/or epiphyseal arrest.¹⁶ Shortening can be accomplished using a partial or complete digital metacarpophalangeal joint resection,⁴⁹ an arthrodesis (particularly for the thumb metacarpophalangeal joint, as long as the carpometacarpal and interphalangeal joints have satisfactory motion),^{9,11,25,28} and a distal interphalangeal joint excision and arthrodesis in the digits.^{11,29,50,57-59} Complete excision of the middle phalanx⁶⁰ has been proposed for severe problems.^{9,16,25,28} Similarly, terminalization (amputation of the distal phalanx, including the nail) has also been described, but is generally not recommended in the hand for cosmetic reasons.^{9,16,25,28} Other procedures include resection of the distal phalanx and the distal part of the middle phalanx, preserving the nail complex as a pedicled island flap,⁶¹ and a partial distal phalangeal tip reduction,⁴⁹ which is a component in several authors' combination techniques.^{49,59,62-64}

Decreasing bony width by resecting a quarter to a third of each side of each phalanx⁹ is thought to reduce articular motion and should probably be reserved for cases in which motion is already greatly reduced, in periarticular areas where arthrodesis is planned, or for cases in which aesthetic considerations outweigh functional ones. Nevertheless, Bertelli et al⁵⁰ reported a case (described previously) of unilateral longitudinal resection of a third of the bony width of the phalanges in an 8-year-old girl in whom metacarpophalangeal and proximal interphalangeal joint motion remained unchanged after 4 years of follow-up. An epiphysiodesis was not undertaken, with the exception of that of the distal phalanx at the time of an arthrodesis of the distal interphalangeal joint. This procedure is worrisome to undertake in young patients with little or no joint stiffness; however, it is not known whether such a surgery would provide better results than those obtained when patients are older; in my experience, ligament reconstruction is superior (less instability and less stiffness) in younger patients (12 to 24 months of age) for other types of congenital hand malformations (for example, thumb duplication). Inspired by the procedure of Bertelli et al, Kakinoki and Ikeguchi⁵⁸ performed an even more aggressive operation in even younger patients (3 years of age). The bony procedures were similar, only with greater shortening of the distal part of the middle phalanx and reduction in the width of the proximal phalanx extending more proximally. The bony reconstruction was then covered using a palmar pedicled and a dorsal island flap, one based on the radial and the other on the ulnar neurovascular digital pedicles. The dorsal flap also included dorsal subcutaneous veins. Despite such extensive surgery, metacarpophalangeal joint motion remained stable, and proximal interphalangeal joint motion actually increased from 40 degrees to 70 degrees at the 3-year follow-up.

Most debulking techniques combine several procedures simultaneously and/or sequentially, often including longitudinal growth arrest or various modalities to correct angulation deformities. Although multiple methods have been described, only Millesi's thumb reduction method⁶⁴ (see Fig. 47-12) and the digital shortening techniques of the following authors will be described and illustrated in this chapter, including the necessary incisions: Barsky²⁹ (see Fig. 47-13), Tsuge⁴⁹ (who now limits his frequently cited 1967 operation³⁰ to treatment of the toes) (see Fig. 47-14), Hoshi et al⁵⁹ (see Fig. 47-15), Fujita et al⁶³ (see Fig. 47-16), Ogino¹¹ (see Fig. 47-17), and Bertelli et al⁵⁰ (see Fig. 47-18).

Millesi's Thumb Reduction Method

Millesi's thumb reduction method⁶⁴ includes resection of the distal phalanx distally and along a central longitudinal strip and shortening of the proximal phalanx using an oblique resection osteotomy (Fig. 47-12). The reduction in width of the distal phalanx is limited by the interphalangeal joint's collateral ligament laxity; the proximal phalanx width is not addressed. Because the distal phalanx osteotomy involves the joint surface, any remaining motion may be limited. A nail deformity in the form of a ridge or a separation often occurs, because soft tissue excision includes the nail bed and root in the midline. An extensor lag may result, which requires tendon shortening. In this case, the tendon may adhere to the underlying osteotomy of the proximal phalanx, further limiting motion.

Fig. 47-12 Millesi's thumb reduction method. **A**, The surgical plan (dorsal view). The distal phalanx is resected distally and along a central longitudinal strip. The strip width is limited by the interphalangeal joint's collateral ligament laxity. Internal fixation can be undertaken using an interosseous wire.¹⁶ The proximal phalanx is shortened using an oblique resection osteotomy. Internal fixation can be accomplished using an interosseous wire and a K-wire perpendicular to the osteotomy.¹⁶ The approach can be through a longitudinal midline incision. Soft tissue excision includes the nail bed and root. The fingertip soft tissue is closed by rotating radial and ulnar skin flaps toward each other. **B**, The postoperative appearance.

Fig. 47-13 Barsky's procedure. **A**, The surgical plan (lateral view). Bone resection includes the distal part of the middle phalanx, the distal phalanx articular surface, and a conical distal phalanx central core, including all or much of the growth plate, to receive the sharpened end of the middle phalanx. Internal fixation can be achieved using a longitudinal K-wire. The extensor tendon is shortened and the deep flexor tendon plicated. Six weeks postoperatively, excess palmar soft tissue can be excised. In a simplification of this technique, transverse osteotomies facilitate resection of the distal interphalangeal joint.¹⁶ (Although this modification is attributed to Flatt,⁹ it does not appear in the cited reference.) **B**, The postoperative appearance.

Barsky

Barsky's procedure²⁹ involves resection of the distal part of the middle phalanx, the distal phalanx articular surface, and the conical distal phalanx central core, including all or much of the growth plate, to receive the sharpened end of the middle phalanx (Fig. 47-13). The extensor tendon is shortened and the deep flexor tendon plicated. Excess palmar soft tissue can be excised 6 weeks postoperatively. Although this technique shortens the longitudinal dimension of the finger to a certain extent, it does not reduce the width, and any motion present at the distal interphalangeal joint is lost. This technique does not address continued proximal or middle phalangeal growth or angulation deformities.

Tsuge

In Tsuge's 1985 operation⁴⁹ the phalangeal growth plates are excised and a tip plasty, including excision of bony and soft tissues, is performed with or without digital soft tissue and unilateral digital nerve resection (Fig. 47-14). Further bone shortening is carried out as needed, beginning with the base of the proximal phalanx, and, if required, the head of the metacarpal. According to Tsuge, in older children, the metacarpal growth plate is left intact to prevent joint stiffness. He did not specify what is done to the metacarpophalangeal collateral ligaments. Using this method, not only is further growth reduced, but length is also significantly reduced, although potentially at the expense of metacarpophalangeal joint stability or motion. On the other hand, the reduction in the width of the digit is more modest, because reduction of the bony contribution to this dimension is not attempted. Although not formally part of the description, this technique could be used potentially to correct proximal angulation deformities but not those located more distally, by including a wedge osteotomy to achieve epiphysiodesis. A resulting extensor lag in cases with more aggressive reduction in length would not be surprising and would require tendon shortening. Tendon adhesions to the operated metacarpophalangeal area may develop in some such cases.

Fig. 47-14 Tsuge's operation. **A**, The surgical plan (lateral view). The phalangeal growth plates are excised, along with bone and soft tissue at the tip of the finger. Additional bone is resected for further shortening, if needed, through a dorsal midline incision, beginning with the base of the proximal phalanx and, if required, the head of the metacarpal. In older children, the growth plate is preserved intact to prevent joint stiffness. Tsuge's article does not specify what is done to the metacarpophalangeal collateral ligaments. Soft tissue resection may be continued proximally in the midlateral line to include hypertrophic nerve and excess skin if debulking is required. **B**, The postoperative appearance.

Originally proposed by Tsuge,³⁰ complete resection of a digital nerve is only indicated in selected cases and usually limited to a single side. Although several authors have reported that patients with macrodactyly do not have a significant reduction in sensation,^{49,50,62} no systematic, double blind, complete, formal evaluation of patients having this procedure has ever been conducted. In my experience, nerve excision does not slow or halt growth and should not be used for this purpose.^{9,49}

Hoshi et al

The technique described by Hoshi et al⁵⁹ consists of a resection osteotomy of the proximal metacarpal, resection of the distal end of the terminal phalanx, and resection and fusion of the distal interphalangeal joint (Fig. 47-15). Soft tissue is excised on the convex side of the digit, including the distal and convex sides of the nail bed and root. The reduction in length is achieved at the expense of the distal phalanx and distal interphalangeal joint, similar to Barsky's operation,²⁹ in addition to further shortening at the metacarpal level. As with Barsky's technique, disadvantages include loss of any motion present at the distal interphalangeal joint. In addition, this technique does not address continued growth of the proximal or middle phalanx or any angulation deformities. On the other hand, there is more reduction in width than with Barsky's operation because of the soft tissue reduction on the convex side of the digit and nail. Reduction in width remains more modest than if a bony procedure had also been included.

Fujita et al

In the shortening method described by Fujita et al,⁶³ length reduction is limited to bone resection of the distal end of the terminal phalanx and excision of the distal dorsal and palmar soft tissues (Fig. 47-16). Width is reduced by removing soft tissue. A proximally based palmar soft tissue flap is created, including the radial neurovascular pedicle. The ulnar third of the flap and the ulnar digital nerve are excised. Reductions in length and width are more modest, because bony reduction in length is limited to one level, and bony width is not reduced. This procedure does not limit continued growth or correct angulation deformities. Once the ulnar digital nerve has been dissected away from the artery and excised, the vascular supply to the dorsal skin and bony

Fig. 47-15 The technique of Hoshi et al. **A**, The surgical plan (lateral view, convex side). Bone resection includes a resection osteotomy of the proximal metacarpal, which can be performed through a dorsal longitudinal incision; resection of the distal end of the terminal phalanx; and resection and fusion of the distal interphalangeal joint, performed through the soft tissue excision sites. Bone is fixated using a K-wire and/or interosseous wire. The intermetacarpal ligament or ligaments must be transected to allow shortening of the digit. Soft tissue excision is performed on the convex side of the digit, including the distal and convex side of the nail bed and root. **B**, The postoperative appearance.

Fig. 47-16 The method of Fujita et al. **A**, The surgical plan (palmar view). Bone resection is limited to the distal end of the terminal phalanx. The proximally based palmar soft tissue flap includes the radial neurovascular pedicle. The distal end and ulnar third of the flap are excised, along with the ulnar digital nerve. The tip is closed with the distal end of the flap. **B**, The postoperative appearance.

skeleton, and even to the palmar flap, may be a concern. Dorsal and ulnar digital sensation merits study. In my experience, and as Flatt⁹ reported, scarring is often hypertrophic in these patients. This may become problematic because of the extent of the incisions.

Ogino

Ogino's procedure¹¹ involves bone resection of the proximal phalanx, including a closing wedge osteotomy to correct angulation, resection of the distal end of the terminal phalanx, and resection and fusion of the distal interphalangeal joint (Fig. 47-17). Soft tissue is excised on the convex side and includes the digital nerve but excludes the digital artery. Similar to the operations described by Barsky²⁹ and Hoshi et al,⁵⁹ the length is reduced at the expense of the distal phalanx and distal interphalangeal joint, and by further shortening at the proximal phalangeal level. This technique

Fig. 47-17 Ogino's procedure. **A**, Surgical plan (dorsal view). Bone resection includes a part of the proximal phalanx and a closing wedge osteotomy to correct angulation, resection of the distal end of the terminal phalanx (which is mentioned in the text, not included in the reference diagrams, but added here), and resection and fusion of the distal interphalangeal joint. Internal fixation can be achieved using K-wires and/or interosseous wires. Soft tissue excision is undertaken on the convex side, including the digital nerve but excluding the digital artery, and closed with interdigitating palmar and dorsal flaps. **B**, The postoperative appearance.

includes the correction of an angulation deformity. As with the techniques of Barsky and Hoshi et al, disadvantages include loss of motion at the distal interphalangeal joint and failure to address proximal or middle phalangeal continued growth. Because of shortening at the proximal phalangeal level, an extensor lag may result, which may require tendon shortening. In this case, the tendon may adhere to the underlying osteotomy of the proximal phalanx, further limiting motion. Sensation on the side of the resected digital nerve merits study.

Bertelli et al

As described previously, Bertelli et al⁵⁰ have performed an operation with the potential advantage of correcting both bony and soft tissue excess in width (Fig. 47-18). Similar to Barsky's procedure,²⁹ bony length reduction is more modest and is limited to shortening at the level of the distal interphalangeal arthrodesis. As with Barsky's, Hoshi's, and Ogino's techniques,^{11,29,59} disadvantages include loss of any motion present at the distal interphalangeal joint, and proximal or middle phalangeal continued growth is not addressed. In addition, the potential for stiffness or instability exists at the proximal interphalangeal joint collateral ligament reinsertion site. This operation does treat angulation deformities. The vascular supply can be a concern, because one neurovascular pedicle is completely resected. As in Tsuge's and Fujita's methods,^{49,63} sensation after complete excision of one digital nerve would merit further study.

In summary, the most aggressive reduction in width is achieved with the operation described by Bertelli et al,⁵⁰ and the techniques of Hoshi et al⁵⁹ and Ogino¹¹ produce the greatest osseous shortening. Epiphysiodesis can be combined with most techniques once the digit is the same length as that of the parent of the same sex. Angulation deformity can often be corrected at the same time as the epiphysiodesis by incorporating a closing wedge osteotomy. The most aggres-

Fig. 47-18 The operation of Bertelli et al. **A**, The surgical plan (dorsal view, right digit). Bone resection includes the ulnar thirds of the distal part of the proximal phalanx, middle phalanx, and terminal phalanx and resection and fusion of the distal interphalangeal joint. Internal fixation can be performed using a K-wire and/or interosseous wire. Soft tissue is excised on the ulnar side, including the ulnar neurovascular pedicle and distal third of the nail bed, and closed with interdigitating palmar and dorsal flaps. The ulnar proximal interphalangeal joint collateral ligament, which is detached from the excised bone, is reinserted through drill holes. Six months postoperatively, the radial side is debulked, preserving the radial neurovascular pedicle. **B**, The postoperative appearance.

sive soft tissue reductions include excision of one digital nerve, as described by Tsuge,⁴⁹ Fujita et al,⁶³ Ogino,¹¹ and Bertelli et al.⁵⁰ The sensory results of this excision merit further study. Tailoring the nail plate is a component of most of the previously described procedures and contributes to normalizing the appearance of the fingertip. No technique is perfect, and most patients require multiple operations in a staged fashion.⁴⁸

POSTOPERATIVE CARE

It is possible to increase postoperative comfort by giving a digital or distal regional bloc at the end of surgery (for example, the median nerve or the ulnar nerve at the wrist) with a long-acting agent such as bupivacaine. The dressing should be sufficiently well padded to protect against pressure points, but it should not cause postoperative compression. This is particularly important when a bloc has been used. Surgeons must anticipate postoperative swelling, which may be substantial if the total tourniquet time is longer than 2 hours or if the surgery is extensive.

Patients who undergo soft tissue surgery alone, especially young children, often benefit from 7 to 10 days of immobilization, which provides comfort and incision protection. Osteotomies and epiphysiodeses necessitate at least 3 weeks of immobilization, depending on the presence of internal fixation and the stability of the technique used for osteosynthesis. Further, full-time or night splinting may be required to protect or adjust the position. Ligament reconstruction or repair should be immobilized for 4 to 6 weeks (4 weeks for patients 2 years of age and younger and 6 weeks for older patients). Subsequently, 6 weeks to 2 months of night splinting is recommended, and sports or other activities that may place strain on the repair are prohibited for this time. Patients who are not stiff and have an increased risk of instability should wear a splint dur-

ing the day and remove it only for scar massage and exercises. After this period, further splinting for up to 1 year is recommended during sports and activities that may place stress on the repair, but patients who have stiffness should not use a splint.

For smaller children or patients with compliance difficulties, we place a well-padded plaster sugar-tong splint. Before the splint is placed, a small amount of Mastisol adhesive or tincture of benzoin is applied to the nonoperated skin of the hand and forearm to minimize motion of the dressing. The plaster strips are applied on the adequately dressed, well-padded limb, beginning on the palmar aspect of the digits, continuing proximally to the elbow (flexed to 90 degrees), and around the distal arm to the dorsal surface, where they continue distally along the forearm to the wrist (Fig. 47-19).

Fig. 47-19 A left upper limb sugar-tong plaster splint seen from the ulnar side, with elbow flexed to 90 degrees.

Fig. 47-20 An elevation technique using a nonelastic cloth tube sleeve.

Regardless of the dressing, postoperative elevation of the limb is highly recommended. We follow the rule “hand higher than elbow higher than shoulder” and use a suspension technique in which a nonelastic cloth tube sleeve is attached around the chest (Fig. 47-20). Its distal end can then be attached to something solid at the desired height. The length of the sleeve between the tips of the fingers and the site of attachment should not be long enough to encircle the neck of the patient. Elevation is easily obtained using this technique and is continued for 7 to 10 days for soft tissue surgery patients and for up to 2 weeks or more for patients with more extensive procedures or pronounced edema. Subsequently, the end of the sleeve can be attached over the opposite shoulder to the back portion of the attachment around the chest, elevating the hand to shoulder level.

As soon as the initial dressing is removed, the patient begins occupational therapy, including splinting, scar massage, the use of topical sheet silicone and/or compressive gloves for the scars (see Chapter 48), and exercises. In my experience, and as others have reported, patients with macrodactyly can develop hypertrophic scars.⁹ Patients are followed until the scars have matured, which may take 1 to 2 years or more. Follow-up continues in the outpatient clinic until the end of growth.

TREATMENT OUTCOMES AND COMPLICATIONS

Despite numerous techniques described in the literature, surgical management of this malformation is difficult, with less than satisfactory results in many cases. The large number of techniques in the literature are proof of this problem. Most surgeons have limited experience with this malformation, because it occurs infrequently, further compounding the problem. Soft tissue debulking techniques alone do not control the increase in bony width and length but may be sufficient for more subtle cases. In more severe forms, techniques that reduce length frequently involve loss of a joint, but most do not correct excess width. Procedures that also address width risk the development of joint stiffness. An epiphysiodesis halts longitudinal growth but does not decrease width. The best outcomes are achieved with combination techniques that treat all aspects. Several operations are frequently required to obtain an acceptable result.⁴⁸

In addition to difficulties in obtaining satisfactory results, complications can occur. These include vascular compromise of the digit; skin flap necrosis; hypesthesia; areas of anesthesia; angulation deformities; malunion or, more rarely, nonunion of epiphysiodeses or osteotomies; limitation of motion or joint instability; hypertrophic scars; and complications related to the dressings and anesthesia, common to all hand surgery.

FUTURE DIAGNOSTIC AND TREATMENT MODALITIES

Further work in molecular biology³⁸ and genetics, such as continued research in somatic mutations,⁴¹ may lead to a better understanding of this heterogeneous condition and provide new treatment modalities.

In the meantime, perhaps more experience with sequential combination techniques such as the operation of Bertelli et al^{50,58} in younger patients, followed by epiphysiodeses and/or closing wedge osteotomies, may improve treatment of these challenging cases.

KEY POINTS

- Careful attention to signs of nerve compression is essential for timely investigation and surgical treatment as indicated.
- Distinguishing between static versus progressive forms of macrodactyly is critical. Sequential comparative bilateral AP radiographs of the hands allow measurements and calculations of percentage differences in the length of various bones (or entire digits as long as no angulation deformity is present). These radiographs are usually obtained at 1-year intervals or longer, unless a clinical concern arises. Progressive forms predictably require a greater number of interventions.
- Because of the complexity in treating macrodactyly, a well-integrated interdisciplinary approach is often useful. Pediatricians and/or medical geneticists can screen for syndromic cases and refer patients to other specialists or multidisciplinary clinics. Occupational therapists and/or physiotherapists can evaluate function, follow for deterioration, and help to plan treatment. Psychologists and/or social workers can assess a patient and family's ability to cope with the malformation and multiple proposed interventions, and support the patient during various stages of treatment and life's milestones, such as starting day care or grade school or entering high school.

For Patients Seen Soon After Birth

- Whether the operation described by Bertelli et al⁵⁰ would provide satisfactory results in a larger number of patients and/or in younger patients is not known, but the technique seems promising. The longitudinal resection should be performed on the side of the digit that requires less collateral ligament stability.
- Epiphysiodesis with or without a closing wedge osteotomy should be carried out to arrest longitudinal growth when the digit reaches adult length.
- Other operations may be required before or after the reduction procedures (for example, carpal tunnel release or isolated closing wedge osteotomies).
- Amputation of a digit may be a reasonable alternative in some cases and should be discussed with the parents as a possible outcome early in the child's care.

For Patients Seen at an Older Age

- The operation described by Bertelli et al⁵⁰ may be considered for patients who are not too old. (The patient described was 8 years of age.)
- Epiphysiodesis should be performed as described previously in the chapter if the patient's digit is equal in length to that of an adult.
- One of the combination techniques can be used in older patients.
- Amputation of a digit may be a viable option.

The author presented a brief description of his 30-year experience beginning in 1985 and included the technique he developed for children with minimal hypertrophy (excision of the phalangeal epiphyseal plates and tip plasty) and children and adults with advanced hypertrophy (tip plasty, with or without soft tissue and unilateral digital nerve excision, with or without metacarpal base or metacarpophalangeal joint resection). He mentioned that amputation should be considered in severe cases. He also admitted that nerve excision did not check the growth of the digit (which he had claimed in his 1967 article).
50. Bertelli JA, Pigozzi L, Pereima M. Hemidigital resection with collateral ligament transplantation in the treatment of macroductyly: a case report. J Hand Surg Am 26:623, 2001.
The authors presented a case report of the surgical technique used in an 8-year-old with macroductyly in whom the unilateral longitudinal third of the bony width of the phalanges was resected, the distal interphalangeal joint was arthrodesed, the soft tissue and ulnar neurovascular bundle were excised, and the proximal interphalangeal collateral ligament was removed and reinserted. Contralateral soft tissue was debulked 6 months later, preserving the neurovascular bundle. At the 4-year follow-up, the range of motion remained unchanged at the proximal interphalangeal and metacarpophalangeal joints.

58. Kakinoki R, Ikeguchi R, Duncan SF. Transverse and longitudinal osteotomy for the treatment of macrodactyly simplex congenita: a case report. Hand Surg 13:121, 2008.
The authors presented a case report of the surgical technique, inspired by that of Bertelli et al, used in a 3-year-old with macrodactyly. Differences included somewhat more aggressive bone reduction and coverage using a volar pedicled and dorsal island flaps, one based on the radial and the other on the ulnar neurovascular digital pedicles. The dorsal flap also included dorsal subcutaneous veins. Despite extensive surgery, metacarpophalangeal joint motion remained stable, and proximal interphalangeal joint motion actually increased from 40 to 70 degrees at the 3-year follow-up. Clinical photographs from the follow-up showed evidence of increasing angulation with growth of both the operated and adjacent involved but unoperated digits.

Congenital Hand Anomalies: Undergrowth

E. Patricia Egerszegi

Although *undergrowth* is traditionally the fifth separate class under the International Federation of Societies for Surgery of the Hand (IFSSH) classification system for congenital hand anomalies,¹ hypoplasia of varying parts of the upper limb is one of the most common clinical features of most of the classes of hand malformations,^{2,3} with the exception of most cases of overgrowth. For this reason, the following malformations are discussed in other chapters in this book:

- Transverse arrest of development, the most severe forms of which are difficult, if not impossible, to differentiate from some forms of undergrowth (Chapters 42 and 51)
- Longitudinal arrest of development, including thumb hypoplasia and central ray deficiencies (Chapters 42 and 43)
- Clinodactyly (Chapter 44)
- Hypoplasia of duplicated elements, including hyperphalangism (Chapter 46)
- Hypoplasia found in constriction band syndrome (Chapters 44 and 49)
- Hypoplasia can also be associated with some giant congenital nevi⁴ (Group II: failure of differentiation of parts—congenital tumorous conditions; however, this subclass is not included in older versions of the Swanson classification system)⁴

Undergrowth can involve the whole limb, the whole hand, or segments thereof, and involves any, several, or all of the structures of the limb. It can be unilateral, bilateral, or involve all four limbs, whereas the distribution pattern can be specific for certain subtypes. It can be isolated or part of a syndrome (Table 48-1 and Box 48-1). In its mildest form, undergrowth requires no treatment; however, in its more severe forms, treatment can be very challenging.

Table 48-1 Associations, Syndromes, or Diseases of Brachydactyly*

Class	Syndromes ⁵⁻¹⁰	Class	Syndromes ⁵⁻¹⁰
I Generalized	Achondroplasia Diastrophic dwarfism Dyschondrosteosis Ellis-van Creveld syndrome Geleophysic dysplasia ^{11,12} Hereditary multiple exostosis Hypochondroplasia Metaphyseal dysostosis Mucopolysaccharidosis (gargoylism) Multiple epiphyseal dysplasia Ollier disease Orofaciodigital syndrome Peters Plus syndrome ¹³ Peripheral dysostosis Smith-Magenis syndrome ^{14,15} Spondyloepiphyseal dysplasia Spondylometaphyseal dysplasia Weill-Marchesani syndrome	IV Type D brachydactyly (stub thumb brachydactyly)	Robinow syndrome Rubinstein-Taybi syndrome Tabatznik syndrome (heart-hand syndrome II) Wiedemann syndrome ²⁴
II Underdeveloped distal phalanges	Cleidocranial dysostosis Coffin-Siris syndrome Fanconi anemia Fetal hydantoin syndrome ¹⁶⁻¹⁸ Gorlin-Chaudhry-Moss syndrome ¹⁹ Keutel syndrome Killian/Teschler-Nicola syndrome (or Pallister-Killian, or Pallister mosaic syndrome, or tetrasomy 12p) ^{20,21} Kirner's deformity Larsen syndrome Nail dysplasia/brachydactyly/distal phalanx syndrome ²² Pallister-Hall syndrome (with syndactyly) ²³ Progeria Pudiger syndrome Pyknodysostosis Sorsby syndrome	V Brachydactyly with polydactyly	Ellis-van Creveld syndrome Orofaciodigital syndrome
III Type A3 brachydactyly (short middle phalanx of little finger)	Coffin-Siris syndrome Cornelia de Lange syndrome Down syndrome Noonan syndrome Oculodentodigital syndrome Orofaciodigital syndrome I and II Otopalatodigital syndrome Poly-X syndrome Rubinstein-Taybi syndrome Russell-Silver syndrome TAR syndrome	VI Brachydactyly with syndactyly (sybrachydac- tyly)	Aarskog syndrome ^{25,26} Aglossia-adactylia Ankyloglossia superior Apert syndrome Cleft palate and lateral synechia Cleft lip Clubfoot ²⁷ Congenital cataract Cornelia de Lange syndrome Ear deformity Foot reduction abnormalities Glossopalatine ankylosis Hanhart syndrome Moebius syndrome Morning glory syndrome Poland syndrome (or sequence) Renal anomalies Submucous cleft palate ²⁷ Summit syndrome ²⁸ Undescended testis: ipsilateral ²⁷
		VII Cone-shaped epiphysis	Acrodysostosis Jackson-Weiss syndrome ²⁹ Langer-Giedion syndrome Myrhe-LAPS syndrome ³⁰ Trichorhinophalangeal syndrome
		VIII Miscellaneous	Bloom syndrome Cleft hand Du Pan syndrome Hand-foot-uterus syndrome Holt-Oram syndrome Osteochondrosis dissecans ³¹ Symphalangism Treacher Collins syndrome

*List includes sybrachydactyly but excludes brachymetacarpia.

LAPS, Laryngotracheal stenosis, arthropathy, prognathism and short stature; TAR, thrombocytopenia-absent radius.

The definition of some of the terms commonly encountered in descriptions of undergrowth of the upper limb^{6,10,32-34} can be found in Box 48-2.

Box 48-1 Some Syndromes or Diseases Associated With Brachymetacarpia* (Including the First Metacarpal)

Acrodysostosis	Cretinism	Multiple exostoses syndrome
Aicardi syndrome	Cri du chat syndrome (deletion 5p syndrome)	Orodigitofacial syndrome
Albright hereditary osteodystrophy	Deletion 4q syndrome	Otopalatodigital syndrome, type I
Banki syndrome	Deletion 18q syndrome	Otopalatodigital syndrome, type II
Basal cell nevus syndrome	Diastrophic dysplasia	Pallister-Hall syndrome (Hall syndrome)
Biemond syndrome	Duplication 9p syndrome	Poland syndrome (or sequence)
Bilginturan brachydactyly	Duplication 10q syndrome	Progressive myositis ossificans
Bixler syndrome	Duplication of uterus	Pseudohypoparathyroidism
Brachydactyly A1	Dwarfism	Pseudopseudohypoparathyroidism
Brachydactyly C	Dyggve-Melchior-Clausen syndrome	Pyruvate kinase deficiency
Brachydactyly E	Ectodermal dysplasia (Bork) ^{35,36}	Robinow syndrome
Campomelic dysplasia	Fanconi anemia	Ruvalcaba syndrome
Catel-Manzke syndrome	Fetal alcohol syndrome	Saethre-Chotzen syndrome
Chondrodysplasia punctata, X-linked dominant type	Gorlin syndrome	Schinzel-Giedion syndrome
Cockayne syndrome	Gorman syndrome	Silver syndrome
Coffin-Siris syndrome	Grebe syndrome	Sybert syndrome
Cohen syndrome	Holt-Oram syndrome	Tabatznik syndrome (heart-hand syndrome II)
Congenital glaucoma	Kabuki syndrome	Taybi-Linder syndrome
Congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD) syndrome	Klinefelter syndrome	Tibial aplasia—ectrodactyly syndrome
Conradis disease	Larsen syndrome	Trichorhinophalangeal syndrome, type I
Cornelia de Lange syndrome (Brachmann—de Lange syndrome, de Lange syndrome)	Leri pleonosteosis	Triploid syndrome
	Leri-Weill dyschondrosteosis	Tuomaala-Haapanen syndrome
	Levy-Hollister syndrome	Turner syndrome (XO, 45X)
	Mseleni joint disease	Ulnar-mammary syndrome
	Multiple epiphyseal dysplasia	Wiedemann syndrome

*Including features described by Gupta and Scheker,⁷ McCombe and Kay,⁸ Jones,³⁷ Jones,³⁸ and Wood.³⁹

Box 48-2 Commonly Used Terms for Describing Upper Limb Undergrowth

adactyly Absence of digits	monodactyly Presence, usually congenital, of only one digit on the hand or foot
brachydactyly Short digit	oligodactyly Subnormal number of fingers or toes (often used to be synonymous with atypical cleft hand and symbrachydactyly*)
brachysyndactyly Short and fused digits	peromelia Absence (or deformity) of the terminal part of a limb
brachymetacarpia Short metacarpal	symbrachydactyly* Previously known as atypical cleft hand (see brachysyndactyly)
brachyphalangia Short phalanx	syndactyly Fusion of digits
brachybasophalangia Short proximal phalanx	
brachymesophalangia Short middle phalanx	
brachytelephalangia Short distal phalanx	
clinodactyly Permanent radial or ulnar deviation of one or more fingers	
ectrodactyly Absence of all or part of a digit (usually used for group I—Failure of formation of parts—longitudinal deficiencies—central); occasionally used for transverse deficiencies)	

*Some authors still differentiate between *symbrachydactyly*, defined as a central loss with hypoplastic digits (and classify it under group I: Failure of formation—longitudinal arrest—central ray deficiency [cleft hand—atypical type]), and *brachysyndactyly*, defined as central syndactyly with short digits (and classify it under group V: Undergrowth—phalangeal [digit]),⁴⁰ rather than consider brachysyndactyly as a less severe form of symbrachydactyly, as done by Yamauchi and Tanabu¹⁰ and in this chapter.

CLASSIFICATION

The IFSSH¹ subclassifies undergrowth first into the area involved:

- 1 = Whole limb
- 2 = Forearm and hand
- 3 = Hand alone
- 4 = Metacarpal
- 5 = Digit

The IFSSH then subclassifies certain categories (Table 48-2). Although no classification system neatly organizes all of the subtypes, the two main categories involving the hand, *brachydactyly* (including brachymetacarpia) and *brachysyndactyly* (now known as *symbrachydactyly*), have each been subclassified by various authors.

Although the first radiographs of brachydactyly were published in 1896⁴¹ and the term coined the same year,⁴² it was not until 1932 that McArthur and McCullough⁴³ first classified the anomaly into two groups: present at birth and evident with growth. One of the first commonly used classification systems for brachydactyly was published by Bell in 1951.⁴⁴ This classification system has since been modified and eponyms added^{7,9,44,45} (Table 48-3), and is the most useful classification system historically from a genetic point of view.

Table 48-2 IFSSH Classification System for Undergrowth

IFSSH System ¹ With Modifications ⁴⁶	Author's Suggested Modifications to the Classification of Undergrowth
	Thoracic muscle $\pm$ chest wall underdevelopment (isolated) ^{47,48}
Whole limb	Whole limb
Forearm and hand	Forearm and hand
Hand alone	Hand alone
Entire	Entire
Partial	Partial
Metacarpal	Metacarpal
Brachymetacarpia	Brachymetacarpia: bilateral or unilateral
Fifth ray	Fifth ray
Other brachymetacarpia	Other isolated ray
Other	Multiple rays
Digit	Digit: most bilateral
Brachysyndactyly	Brachydactyly
With absence of thorax muscles (Poland syndrome)	Brachymesophalangia
Without absence of thorax muscles	Brachytelephalangia
Brachydactyly	Brachybasophalangia
Brachymesophalangia	Symbrachydactyly: most unilateral
Defect of two or more phalanges	With thoracic muscle absence $\pm$ chest wall underdevelopment (Poland syndrome)
Defect of proximal or distal phalanx	Without thoracic muscle absence
Other	

Table 48-3 Modified Bell Classification System for Brachydactyly

Classes	Particular Features
Type A	
A1: Farabee brachydactyly	Short middle phalanges in all digits, when severe, absent, or fused to distal phalanges; variable grades of severity exist; thumb and big toe proximal phalanges are also involved
A2: Mohr-Wriedt brachydactyly (brachymesophalangy II)	Short middle phalanges of index fingers (which can be delta shaped) and second toes; radial deviation of the index fingers; type A2 is the rarest form of brachydactyly
A3: Bauer brachydactyly-clinodactyly (brachymesophalangy V)	Short middle phalanges of little fingers (which can be delta shaped, causing classic little finger clinodactyly with radial deviation [NOTE: In Gupta et al, ⁷ incorrectly written as ulnar deviation]); transmission is autosomal dominant ⁴⁴ ; more rare in white and black populations (~1%) and very common in Japanese (~21%) ⁴⁹
A4: Temtamy brachydactyly (brachymesophalangy II and V)	Short middle phalanges of index and little fingers; depending on the author, ring fingers (with associated radial deviation) and even middle fingers can be involved; thumbs can present duplication of the distal phalanges; feet have short middle phalanges of all toes and other deformities (such as talipes calcaneovalgus); short stature may be present; autosomal dominant transmission
A5: Bass brachydactyly	Absence of middle phalanges and hypoplastic nails in all four limbs or only upper limbs; may have distal phalangeal hypoplasia or thumb distal phalangeal duplication; autosomal dominant transmission
Type B: Mackinder brachydactyly	Short middle phalanges, absent or rudimentary distal phalanges; nails of index finger through little finger often absent; distal phalanges of thumbs and big toes, when involved, are flat or duplicated; toes 2 through 5 are often involved but less so than fingers; can have symphalangism or syndactyly (which would then be symbrachydactyly ⁷)
Type C: Drinkwater brachydactyly	Short index finger and middle finger middle phalanges; delta middle phalanges of little fingers; hypersegmentation of the index finger and middle finger proximal phalanges; ulnar deviation of the index fingers; normal ring fingers; occasional shortening of metacarpals or symphalangism
Type D: Breitenbecher brachydactyly (stub thumb brachymegalo-dactylysm)	Also known as “Potter’s thumb” or “murderer’s thumb”; short, wide thumb distal phalanges with disproportion between base of distal phalanges and head of proximal phalanges (the base is wider); seen in Rubinstein-Taybi and Tabatznik (heart-hand syndrome II) syndromes and resembles thumb involvement in type B brachydactyly
Type E: Bell brachydactyly (brachymetacarpia-metatarsia)	Short metacarpals (one or more) with or without metatarsals; normal phalanges; often associated with short stature, can have hyperlaxity; often a feature of other types of brachydactyly in addition to several syndromes; when part of Albright’s hereditary osteodystrophy, it is X-linked; in Turner syndrome, it is associated with the XO chromosomal anomaly; autosomal dominant with variable expression in its isolated form
E1 ⁵⁰	Involves fourth metacarpals and metatarsals only
E2 ⁵⁰	Variable metacarpal involvement with some phalangeal shortening (second and fifth metacarpals, index and middle finger distal phalanges, index and little finger middle phalanges)
Other types	
Combined B and E: Pitt-Williams brachydactyly	Ulnar distal phalangeal shortening with involvement of one or more metacarpals; not associated with short stature
Sugarman brachydactyly	Proximal phalangeal shortening with symphalangism; duplication of first toes

On the other hand, *brachysyndactyly* (syndactyly), which was first described by Poland in 1841,⁵¹ was not classified until 1921 into those cases associated with a pectoral muscle defect (*Poland syndrome*) and those without.⁵² Blauth and Gekeler⁵³ later postulated that the condition had a spectrum of severity and classified the malformation into four types.^{10,32,53}

1. *Short finger*: Syndactyly and anywhere from mild brachymesophalangism to complete middle phalanx aplasia of one or several digits, with or without stiffness and/or syndactyly, excluding the thumb—the most common form (33% to 59%)³²
2. *Oligodactyly, cleft hand* type (previously known as *atypical cleft hand*, a term no longer in use): Absence of one or several central digits (11% to 27%)³²
3. *Monodactyly*: Presence of the thumb and replacement of the remaining digits with vestigial nail-bearing nubbins—the rarest form (11% to 17%)³²
4. *Peromelia*: Adactyly and small bumps, which may or may not bear vestigial nails—the second most common form (20% to 23%)³²

Yamauchi and Tanabu¹⁰ subsequently expanded on this idea by developing what is presently the most useful classification system for syndactyly. This system classifies the anomaly according to the specific anatomic features and level of bony absence, thus facilitating treatment planning¹⁰ (Table 48-4 and Fig. 48-1).

Table 48-4 Yamauchi and Tanabu's Classification System for Syndactyly

Classes (percentage in this series)	Particular Features*
Unilateral syndactyly (98%)	Least severe forms have cutaneous syndactyly; all sporadic
Triphalangeal type (16%)	Shortness of some phalanges (usually severe shortening of middle phalanx, moderate shortening of central three distal phalanges, mild in other phalanges); mild shortness of metacarpals; absence of pectoral muscles in 82%
Diphalangeal type (15%)	Absence of one phalanx (usually middle phalanx) in one or more digits (usually central three digits); in those digits where present, this phalanx is severely shortened; other phalanges and metacarpals shorter than in previous type; absence of pectoral muscles in 56%
Monophalangeal type (10%)	Only one phalanx present in one or more digits (usually middle finger, followed by ring and index fingers); severely shortened proximal phalanges of central three digits; shortened distal and moderately shortened proximal thumb phalanges; metacarpals shorter than in previous type. Absence of pectoral muscles in 27%.
Aphalangeal type (24%)	All phalanges absent in one or more digits (usually central three digits); severe metacarpal shortening in central three digits and moderate in border digits; moderate shortening of forearm bones in over half the cases; decreased presence of syndactyly; absence of pectoral muscles in 20%
Ametacarpia type (15%)	One (thumb) or no digits present; severely shortened or absent metacarpals; moderate shortening of forearm bones in most cases; absence of syndactyly; similar to transverse arrest of development; no absence of pectoral muscles in this series
Acarpia type (10%)	Partial or complete absence of carpal bones with partial or complete fusion between those remaining, when present; marked shortening of forearm bones in most cases; absence of pectoral muscles in 18%
Forearm amputation type (8%)	Marked shortening of forearm bones; no absence of pectoral muscles in this series
Bilateral syndactyly (2%) (as high as 7% in other series)	Must differentiate from constriction band syndrome and cleft hand; no absence of pectoral muscles in this series

*Definitions of shortening as a percentage of the normal side: severe $\geq 65\%$; moderate 66% to 80%; mild 81% to 95%.

Fig. 48-1 Yamauchi and Tanabu's classification system for symbrachydactyly (Blauth and Gekeler's classification indicated in parentheses). **A** and **B**, Posteroanterior radiograph and clinical photograph of triphalangeal symbrachydactyly (*short-finger type*) of the right hand. The malformation is limited to mild skeletal shortening affecting the middle phalanges, similar to that in brachydactyly. There is also the presence of frequently encountered clinodactyly of the index through little fingers. **C** and **D**, Posteroanterior radiograph and clinical photograph of diphalangeal symbrachydactyly (*short-finger type*) of the left hand. **E** and **F**, Posteroanterior radiograph and clinical photograph of monophalangeal symbrachydactyly (*short-finger type*) of the left hand. The clinically palpable proximal phalanx of the long finger is not yet calcified and thus is not visible. **G** and **H**, Posteroanterior radiograph and clinical photograph of aphenalangia symbrachydactyly (*oligodactyly*) of the left hand. Marked clinodactyly of the index finger is evident. **I** and **J**, Posteroanterior radiograph and clinical photograph of ametacarpia symbrachydactyly (*oligodactyly*) of the left hand. Typical clinodactyly of the little finger in radial deviation and central digital nubbins is present.

Continued

Fig. 48-1, cont'd **K** and **L**, Anteroposterior radiograph and clinical photograph of acarpia symbrachydactyly (*peromelia*) of the right forearm and hand. None of the carpal bones are visible, because they have not yet ossified. **M** and **N**, Anteroposterior radiograph and clinical photograph of forearm amputation symbrachydactyly (*peromelia*) of the right upper limb. **O**, Anteroposterior radiograph with complete absence of the upper limb and clavicle. **P**, Complete absence of the right upper limb with a vestigial nubbin at the shoulder and a normal left upper limb. **NOTE:** Although this form is not part of the original Yamauchi and Tanabu classification system, it is hereby suggested that it be included and has been added for completeness.

In the past, *brachysyndactyly*, which means short webbed fingers, was considered to be different from atypical cleft hand⁵⁴ and transverse deficiencies.^{1,55} Blauth and Gekeler⁵³ suggested that they were all variants of the same teratologic entity and named them *symbrachydactyly* (the term that will be used from here on). They have in common central ray reduction anomalies with developmental arrest of the second, third, and fourth digits.⁵⁵ The term *atypical cleft hand* (formerly synonymous with what is now *oligodactylic symbrachydactyly*)^{32,56} in the Blauth and Gekeler classification system,⁵³ was abandoned by the Congenital Hand Committee of the IFSSH in 1992.^{32,57} The terms *monodactylic* and *peromelic symbrachydactyly* (in the Blauth and Gekeler classification system⁵³) have likewise replaced certain terminal transverse arrests.³² *Symbrachydactyly* should therefore replace *brachysyndactyly* in the IFSSH classification system; the term should probably be dropped to avoid confusion, or at most should refer only to what used to be known as *short-finger brachysyndactyly* in the Blauth and Gekeler classification system⁵³ (see Table 48-2).

PATIENT CHARACTERISTICS

Because various types of undergrowth are a feature of many other congenital hand malformations, the incidence of undergrowth is unknown in its most generalized form. Some investigators have nevertheless reviewed their experience in congenital hand anomalies to try to establish the frequency of various malformations. In Flatt's series⁵⁸ of 2758 cases of hand malformations, the incidence of brachydactyly was 5.2% (143 cases), making it the sixth most frequent of all of the congenital anomalies, and the incidence of Poland syndrome was 2.2% (60 cases). Because amputations (186 cases [6.8%]) and whole-hand hypoplasia (27 cases [1.0%]) were in separate classes, it is possible that some of these were in fact cases of undergrowth. Flatt⁵⁸ also referred to the Yokohama series, in which brachydactyly was the third most common deformity (19 [7.0%] of 256 cases), and brachysyndactyly the tenth most common (10 [4.0%] of 256 cases). In this series, amputation (16 [6.0%] of 256 cases) and microdactyly (5 [2.0%] of 256 cases) were likewise classified separately, possibly including some cases of undergrowth. Cheng et al² noted a 4.3% incidence of undergrowth among 578 patients with upper limb congenital anomalies who were seen over a 10-year period at their center. Ogino et al⁵⁵ found the incidence of symbrachydactyly to be 4.5% (43 cases/955 hand anomalies) and brachydactyly 4.0% (38 cases/955 hands) in patients seen over a 16-year period.

Although these numbers give some idea of the proportion of hand malformations that these deformities occupy, they do not reflect the actual incidence in the general population. Because some congenital hand malformations are dealt with in the neonatal nursery, they may never be accounted for, such as narrow pedicled polydactyly. Other deformities are missed, such as mild brachydactyly, whereas others are never seen in consultation, such as mild clinodactyly or severe deformities with life-threatening associated conditions. In addition, variability among observers, variability by the same observer over time, and differences among various ethnic backgrounds² and areas of the world may also affect the total number of hand malformations registered, making precise statistics impossible.

Additional factors that confuse the picture include difficulties in classifying certain malformations such as symbrachydactyly, which are variously classified as: failure of formation—transverse arrest; failure of formation—longitudinal arrest—central ray deficiency (cleft hand)—atypical type; and undergrowth.⁴⁶ Cheng et al² underlined this problem when trying to classify the spectrum of transverse arrests, atypical cleft hand, and brachysyndactyly. Furthermore, modifications in the classification system itself have contributed to the confusion rather than clarified the picture. In the past, some authors have placed symbrachydactyly under failure of formation—longitudinal arrest—central ray deficiency (cleft hand)—atypical type, and brachysyndactyly under undergrowth—phalangeal (digit),⁴⁰ claiming that symbrachydactyly, brachysyndactyly, and brachysymphalangism should not be grouped together.⁵⁹ Others argue that brachysyndactyly, atypical cleft hand, and transverse deficiencies are all variants of the same teratologic entity and should all be called *symbrachydactyly*.⁵³ In this chapter, I think that brachysyndactyly, atypical cleft hand, and certain transverse deficiencies are variations of symbrachydactyly and should all be classified under group V: Undergrowth, in the IFSSH system.

There are few reports of actual incidences of certain congenital hand malformations in specific general populations.^{60,61} Castilla et al⁶⁰ evaluated a total of 599,109 live births in 60 South American hospitals participating in the Latin American Collaborative Study for Congenital Malformations. The incidence of symbrachydactyly with Poland syndrome was 0.00002% (12/599,109). Unfortunately, it is unclear whether all cases of symbrachydactyly without Poland syndrome are

accounted for in this paper (if so, its incidence would be 0.00003% [18/599,109]), and it is possible that mild cases of both Poland syndrome and isolated symbrachydactyly were missed.⁶⁰ In addition, several patients who would likely be included in this category today were possibly classified elsewhere. In the report by Freire Maia and Azevedo,⁶¹ a house-to-house survey in central Brazil revealed two cases of Poland syndrome in 58,761 births (0.00003%), whereas cases now considered symbrachydactyly are grouped variably in other categories and cannot be extracted from the data. Although these papers provide some idea of the frequency with which symbrachydactyly in Poland syndrome occurs, they do not refer to other forms of undergrowth, nor do they provide insight about the percentage of all congenital hand anomalies with this diagnosis.

In general, it can be said that brachydactyly, as classified by Bell and modified by subsequent investigators,^{7,9,44,45} refers mostly to bilateral deformities, some involving all four limbs, with various known or suspected inheritance patterns. Many of these are autosomal dominant, and several can be associated with various syndromes (see Table 48-1 and Box 48-1) (Fig. 48-2). The latter vary in inheritance patterns from autosomal dominant (such as Apert syndrome,⁶² which is best classified under group VII: Generalized skeletal abnormalities, but is included by some in group V: Undergrowth) to sporadic (such as Ollier disease).⁶³

Brachymetacarpia, which can be unilateral, bilateral, or can even involve one or both feet, is frequently associated with phalangeal hypoplasia⁶⁴ and thus brachydactyly. It is found in numerous diseases and syndromes^{7,8,37-39} (see Tables 48-1 and 48-3), some of which have an autosomal dominant pattern of heredity. It is of note that little-finger brachymetacarpia is more common (64%) in children with familial short stature compared with those with normal growth (21.7%).^{65,66} Symbrachydactyly (brachysyndactyly), on the other hand, is much more frequently unilateral and sporadic. It may or may not be associated with ipsilateral pectoral hypoplasia (that is, Poland syndrome, which varies in frequency from 22%¹⁰ to 40%⁶⁰ of cases of symbrachydactyly, depending on the study).

There are some forms of digital undergrowth that do not neatly fit into any of these categories and nevertheless qualify as undergrowth. There is little information regarding sex distribution in most of the references cited, with the exception of Castilla et al,⁶⁰ who noted a higher male prevalence for symbrachydactyly with or without Poland syndrome (60%).

Various anomalies have been found to be associated with undergrowth. Clinodactyly, symphalangism, syndactyly, and pectoral muscle hypoplasia (the latter two now considered features of symbrachydactyly),⁸ as well as polydactyly, cleft hand (the latter possibly referring to some

Fig. 48-2 Bilateral brachydactyly. The left and right hands of a patient with trisomy 9.

cases of “atypical” cleft hand, now considered a form of symbrachydactyly), Kirner deformity, and osteochondrosis dissecans of the finger,⁹ among others, can be associated with brachydactyly. Adactylia, peromelia, foot reduction anomalies, clubfoot, ear malformations, cleft lip or palate, Moebius syndrome, and ipsilateral renal hypoplasia or aplasia have been reportedly associated with symbrachydactyly,¹⁰ as have the following syndromes: aglossia-adactylia, ankyloglossia superior, glossopalatine ankylosis, Hanhart syndrome, cleft palate–lateral synechia, morning glory syndrome, and Poland syndrome, among others.³² It is important to note that the previously described associated anomalies and syndromes are subject to the difficulties caused by confusion over previous methods of classification of undergrowth. Hopefully there will be eventual reorganization, clarification, and worldwide adoption of a better classification system that will permit clearer associations between anomalies or syndromes and the various subclasses of undergrowth.

Hand Characteristics

Brachydactylies, as classified by Bell and previously mentioned, are frequently bilateral, and some also involve the feet. The bones most frequently affected are the middle phalanges, which are also the last to ossify.⁶ The index and little fingers are the most frequently implicated with this anomaly.^{6,64} After little-finger middle phalanx reduction, the next most frequent form of hypoplasia is that of the distal phalanx.⁶ These fingers may or may not be associated with nail hypoplasia or aplasia.⁶ There can be associated clinodactyly, symphalangism, or syndactyly⁸; when syndactyly is present, the case is likely a form of symbrachydactyly. Specific forms of brachydactyly can have characteristic involvement of other bones and/or rays in addition to those previously mentioned (see Tables 48-1 and 48-3).

As classified by Yamauchi and Tanabu,¹⁰ symbrachydactyly is most often unilateral, having been identified 95.8% of the time when they combined their own cases with those they refer to in the literature, although bilateral cases do occur (Fig. 48-3). Depending on the reference, unilateral involvement is either relatively equal in distribution between the left and right sides,⁶⁷ more often found on the left (60.6% to 75% of cases),^{10,53} or even more frequent on the right (73.3% if both symbrachydactyly and Poland syndrome are combined; 75% if only Poland

Fig. 48-3 Bilateral symbrachydactyly. **A**, Diphalangal type on the left and acarpia type on the right, as classified by Yamauchi and Tanabu. These would be classified as short finger type on the left and peromelia on the right in Blauth and Gekeler's classification system. **B**, Posteroanterior radiograph of the left hand. **C**, Posteroanterior radiograph of the right hand.

Table 48-5 Features Aiding in Differentiation Between Symbrachydactyly, Cleft Hand, and Amniotic Band Syndrome*

Features	Symbrachydactyly	Cleft Hand	Amniotic Band Syndrome
Heredity	Usually sporadic	Frequently hereditary (autosomal dominant)	Sporadic
Limbs involved	Usually one limb (frequently upper, but lower has been reported ⁶⁸)	One to four (frequently bilateral upper limbs, feet often involved)	One to four in any combination of upper and/or lower limbs
Proximal upper extremity	Forearm/arm hypoplasia; frequent pectorothoracic abnormality	Normal	Normal
Shape of defect	U	V	Frequently straight line (transverse or oblique)
Nubbins	Present in oligodactylic (aphalangia) type; frequent presence of fingernails; no edema	No	Occasional (associated with amniotic band mark); rare presence of fingernails except distal to amniotic band mark if distal phalanx is present; can have edema distal to amniotic band mark
Acrosyndactyly†	No	No	Occurs
First web syndactyly	Mild or none	Occurs	Rare (if so, acrosyndactyly)
Bony abnormalities	Middle, proximal, then distal phalanx, followed by metacarpal hypoplasia; no transverse bones; no synostosis (osseous syndactyly)	Distal to proximal involvement; transverse bones possible; possible synostosis (osseous syndactyly)	Distal to proximal involvement; “jumbled” bones possible; possible osseous acrosyndactyly
Direction of digital involvement with increasing severity	Radial to ulnar (last remaining single digit is the thumb); begins with index and middle fingers	Central to radial (last remaining digit is the little finger); begins with middle finger	None
Number of rays involved	Multiple	Few	Variable, but often involves the longest digits (index through little fingers)
Metacarpal length	Shorter than normal	Normal or longer than normal	Normal

*Including features described by Büchler,³² Kay and McCombe,⁵⁶ and Buck-Gramcko⁶⁹ with modifications.

†Syndactyly between the distal parts of the digits with persistence of a slit or sinus between the bases of the involved digits.

syndrome cases are included).⁶⁰ According to Yamauchi and Tanabu,¹⁰ the malformation spans a spectrum of severity ranging from simple reduction in length, without any bony absence, to loss of part of the forearm (Table 48-5). They stated that the order of bony hypoplasia, followed by absence, begins with the middle phalanx, progresses through the presence of only one phalanx (the proximal one), loss of the metacarpal,⁷⁰ loss of carpal bones, and finally severe shortening of the forearm.¹⁰ It is hereby suggested that complete absence of the limb with one or several small nubbins present at the shoulder be considered part of this progressive sequence (see Fig. 48-1, *O* and *P*). The middle finger ray is the first affected, followed by the index and ring finger rays, then the little finger, and finally the thumb ray.¹⁰ Vestigial elements of digits remain at the distal end of the limb in the form of nail elements and/or soft tissue “buds.”^{70,71} Castilla et al⁶⁰ mentioned that there may be nail hypoplasia of the index finger or thumb. Clinodactyly of the remaining digits is not uncommon^{32,60} (see Fig. 48-1, *G* and *H*), whereas joint stiffness (often interphalangeal) or instability (metacarpophalangeal or interphalangeal) can occur, particularly in the little finger in oligodactylic types.³² More proximally, in the forearm, there may be minor hypoplasia,³² which is progressively more pronounced with increasing severity of the malformation.¹⁰

Fig. 48-4 Bilateral metacarpal hypoplasia most pronounced in the right fourth metacarpal, but also affecting the third metacarpal and the left hand to a lesser extent. **A**, Posteroanterior radiograph of the right hand. **B**, Clenched fists showing the marked right fourth brachymetacarpia.

The thoracic muscles (particularly the sternocostal head of the pectoralis major), the breast, and even elements of the chest wall may or may not be absent or underdeveloped.^{10,32,71} There have been cases reported of isolated partial absence of the pectoralis major muscle with associated breast asymmetry without hand involvement,⁴⁸ and even a case of isolated pectoralis muscle absence in a patient whose second cousin had full Poland syndrome.^{47,72}

Isolated brachymetacarpia tends to affect the ulnar two rays more so than the radial rays.^{6,9} Nevertheless, any single ray can be involved in isolation; the third through fifth rays together can be hypoplastic, as can all the metacarpals.³⁹ Other combinations of several metacarpals have also been described^{6,7,9} (Fig. 48-4). When isolated, isolated brachymetacarpia rarely has a significant functional impact.^{6,39} There is little information in the literature regarding the relative incidence of bilaterality versus unilaterality, and sidedness in unilaterality, for isolated brachymetacarpia.

ETIOLOGIC FACTORS AND PATHOLOGY

Many *bilateral* or *four-limb malformations* (that is, brachydactylies and brachymetacarpias) have been shown to have a genetic cause resulting from various mutations or deficiencies in cartilage-derived morphogenic protein, such as Grebe and Hunter-Thompson chondrodysplasias,⁸ or the bone morphogenic protein pathway.⁷³

Among unilateral deformities, such as most cases of symbrachydactyly, there seems to be a mesodermal abnormality that explains the persistence of ectodermal structures (that is, pulp, nails).⁸ The hypothesis is that the skeletal precursor is abnormal in differentiation or formation with secondary soft tissue deficiency.³² There is a theory that Poland syndrome, as well as Klippel-Feil anomaly, Moebius syndrome, isolated absence of the pectoralis major with breast hypoplasia, isolated transverse limb defects, and Sprengel anomaly, all result from early interruption of the vascular supply in the subclavian artery, vertebral arteries, and/or their branches.⁷⁴ Although there is some support for this, including impedance plethysmography results in eight patients with Poland syndrome, as reported by Bouvet et al,⁷⁵ consistent with hypoplasia of the subclavian artery on the affected side, most published cases have had no vascular imaging. There was even a case published in which the abstract states that there was no arterial anomaly, but it does

Fig. 48-5 Brachymetacarpia with associated fusion of the fifth metacarpal to the adjacent fourth metacarpal in a patient with thumb hypoplasia. **A**, Posteroanterior radiograph of the right hand. **B**, Right hand.

not specify how the arterial system was imaged, nor even refer to this point in the article text.⁷⁶ There have been published cases equivalent to Poland syndrome of the lower limb with unilateral gluteal hypoplasia and brachysyndactyly (sybrachydactyly)^{68,77} and cases of sybrachydactyly with involvement of both the hand and foot.^{78,79} There have even been reports of familial cases of upper limb Poland syndrome⁸⁰ and of gluteal involvement with phenotypic heterogeneity.⁸¹ These cases provide support for a genetic cause in certain patients with Poland syndrome.

Although sporadic cases may be multifactorial, a genetic error during mitosis generating a mosaic of somatic daughter cells that influence the development of the limb could be a factor.⁸⁰ The timing of this error might explain the phenotype and severity of the malformation.⁸⁰ The vascular anomaly, when present, might be the result of this process rather than its cause.

Anatomically, brachydactyly and brachymetacarpia, in their general forms, are limited to shortening and/or hypoplasia of the involved skeletal element, regardless of whether this includes the associated joint or joints, such as the fusion of two phalanges or symphalangism⁷⁻⁹ (see Table 48-4). Involved phalanges may have a delta abnormality with associated clinodactyly⁷⁻⁹; that is, in increasing order of severity, the abnormal bone varying from a trapezoidal bone, a longitudinal epiphyseal bracketed bone, a triangular bone (see Chapter 45) according to the subclass. Nails may be normal, hypoplastic, or absent according to the subtype⁷⁻⁹ (see Table 48-4). Hypersegmentation of the proximal phalanx is a feature of type C Drinkwater brachydactyly, in which there may also be deviation of the index finger in an ulnar direction.⁶ Brachymetacarpia may occasionally include fusion to the adjacent metacarpal⁶ (Fig. 48-5), a feature which can occur as a separate entity, a form of ulnar hypoplasia, or an anomaly common to several other hand malformations.⁹ Some forms, such as type B Mackinder brachydactyly, can have associated syndactyly (see Chapter 45 section on soft tissue abnormalities) and therefore should be classified as sybrachydactyly.⁷

In cases of sybrachydactyly, anatomic anomalies may be limited to mild skeletal shortening, similar to brachydactyly, in the triphalangeal type, affecting the middle phalanges (see Fig. 48-1, *A* and *B*), with or without flexion contractures at the interphalangeal joints, or stiffness, particularly at the distal interphalangeal joints.⁸² Even the thumb may have some signs of hypoplasia, and its metacarpophalangeal joint may also be stiff.⁸² Some degree of clinodactyly may be present with ulnar deviation of the index finger and radial deviation of the ring finger.⁸² In some cases, the radial two digits (excluding the thumb) may deviate ulnarly and the ulnar two may deviate radially (see Fig. 48-1, *A* and *B*), but there are exceptions (Fig. 48-6).

Fig. 48-6 Triphalangeal symbrachydactyly. **A**, Posteroanterior radiograph of the left hand showing clinodactyly with radial deviation of the index finger. **B**, Left hand after sequential syndactyly releases; the index finger would benefit from correction for clinodactyly.

As severity increases, the middle phalanges of the involved digits are absent (diphalangeal type) (see Fig. 48-1, *C* and *D*). The central digits are usually more severely affected than the border ones,¹⁰ although some authors note more involvement of the radial digits (excluding the thumb).^{32,69} The interphalangeal joints may be stiff or unstable.⁸² There is a certain degree of clinodactyly of the digits, particularly of the little finger.⁷¹ There is often syndactyly, particularly but not always⁶⁴ at the fourth web.⁷¹ As severity progresses, the affected digits contain a single phalanx (monophalangeal type) (see Fig. 48-1, *E* and *F*), and are replaced by soft tissue nubbins in the aphalangia type, while maintaining vestigial nail elements^{10,32} (see Fig. 48-1, *G* and *H*). The metacarpals become progressively more hypoplastic as the severity increases.^{10,71}

The digital nubbins can be attached to the extrinsic flexor and extensor tendons through an aponeurotic system. The flexors are often conjoined to various degrees⁸² and activated by a common muscle mass.^{71,82} The extensors, on the other hand, tend to remain separate, including the extensor indicis proprius and extensor digiti minimi tendons.⁷¹ Despite the presence of several vestigial digital nubbins, the little finger remains the best preserved of the digits excluding the thumb. It can have a hypoplastic or absent middle phalanx and a variably stable (unstable to stiff) single interphalangeal joint.^{71,82} The digit tends to deviate in a radial direction because of the pull of the extrinsic extensor (or extensors),^{32,71} and it may have little or no active flexion in some cases⁸² or instability in others.³² The thumb may have hypoplastic phalanges (more so at the proximal phalanx level) or an absent proximal phalanx,⁷¹ and may even have characteristics of thumb hypoplasia.^{71,82} The nail and pulp are smaller.⁷¹ When the distal phalanx is present, the interphalangeal joint can be unstable, but the basal joint may have adequate motion and stability.⁷¹

As severity increases, the little-finger phalanges are reduced to one and finally disappear, leaving a soft tissue nubbin in place of the finger. All of the metacarpals are hypoplastic, even that of the thumb, which then has an underdeveloped basal joint.⁷¹ The thumb proximal phalanx may be present or even absent,⁷¹ and the distal phalanx may be hypoplastic (see Fig. 48-14, *A* and *B*). The intervening joint is hypoplastic and often unstable. The extrinsic flexors of the absent fingers are conjoined into a mass, as are the extrinsic extensors, although the extensor indicis proprius and extensor digiti minimi may still be distinct.⁷¹ The flexors and extensors are fused together through an aponeurotic plane that produces variable amounts of motion or puckering of the

Fig. 48-7 Acarpia symbrachydactyly (peromelia). **A**, An anteroposterior radiograph of the left upper limb, in which there is synostosis between the radius and ulna. **B**, Left upper limb.

finger nubbins.⁷¹ The wrist tendons, particularly the extensors, tend to remain relatively normal.⁷¹ The greater the motion—that is, flexion and extension—of the nubbins or wrist, the more likely it is that the involved tendons have useful excursion.⁷¹

Finally, in the peromelic cases (ametacarpia [see Fig. 48-1, *I* and *J*], acarpia [see Fig. 48-1, *K* and *L*], and forearm amputation types [see Fig. 48-1, *M* and *N*]), there is transverse absence at or proximal to the metacarpal row. Synostosis can occur between the remaining hypoplastic metacarpals, but more frequently between the carpal bones,⁸² and even between the radius and ulna (Fig. 48-7). Wrist tendons may remain⁷¹ if some bony elements of a wrist are present. Vestigial digital tendons with minimal excursion may still be present.⁷¹ The most severe form of symbrachydactyly (rather than a subclass of failure of formation—transverse arrest) is one or several vestigial nubbins attached to the shoulder with complete absence of the humerus and all other elements distally (see Fig. 48-1, *O* and *P*).

In terms of innervation, in more severely affected hands, useful intrinsic function is absent and nerve abnormalities occur.⁷¹ The radial nerve remains, but the ulnar nerve, and with absence of the thumb, even the median nerve are hypoplastic or absent.⁷¹ Rarely, all major nerves in the hand are absent.⁷¹ In cases of undergrowth, vascularization can also be abnormal. The division of the common digital artery into the two proper digital arteries can be more distal than usual, particularly in symbrachydactyly.^{4,69} In rare cases of symbrachydactyly, one of the two proper digital arteries may even be absent.⁴

PATIENT ASSESSMENT

It is essential to examine the hands in detail. This includes determination of which rays are hypoplastic, to what extent, and at which level; the presence of thenar (or even hypothenar) hypoplasia; digital malposition, such as thumb adduction with or without supination⁸²; the presence of syndactyly, to what extent, and in which spaces; joint stability and mobility, both active and passive; and finally, hand function, including tendencies, compensations, and problems. An occupational therapy assessment is very helpful in evaluating the hands and can help in the development of an appropriate treatment plan.

Next, it is essential to examine the rest of the limb, pectoral girdle muscles, and thoracodorsal structures to check for limb length discrepancy or Poland syndrome (Fig. 48-8). Poland syndrome usually involves a pectoralis major muscle defect (usually absence of the sternocostal head, but possibly more extensive) and associated symbrachydactyly (that is, often index, middle, ring, and little finger brachydactyly, occasionally thumb brachydactyly, digital syndactyly, and hand

Fig. 48-8 Poland syndrome. **A**, A right pectoralis major muscle defect is visible. **B**, Right hand symbrachydactyly after multiple syndactyly releases.

hypoplasia).⁷² There may also be other pectorothoracic anomalies, such as breast hypoplasia,⁸³ nipple and/or rib hypoplasia,⁶⁰ absence of the pectoralis minor muscle,⁸⁴ latissimus dorsi muscle hypoplasia,⁸³ Sprengel deformity, scoliosis,¹⁰ or hypoplasia of the ipsilateral lower limb with absence of toes.⁸⁵

Because many associations, diseases, and syndromes (see Table 48-1 and Box 48-1) can accompany certain undergrowth deformities, it may be appropriate to refer the patient to a medical geneticist, other specialists, or an interdisciplinary team to evaluate, treat, and follow associated problems. Finally, it is helpful to identify the exact diagnosis for the hand anomaly, if possible, to help aid in counseling and management of the child and family. Such features as unilaterality/bilaterality, involvement of the lower limb (or limbs), and pectoral and/or pelvic girdle help differentiate between brachydactyly and symbrachydactyly. Nevertheless difficulties can arise occasionally in distinguishing between symbrachydactyly, cleft hand, and amniotic band syndrome. Several features can help differentiate between these malformations (see Table 48-5).

Comparative radiography of the normal (if present) and involved sides (including, if indicated, and in cases of symbrachydactyly, scanography to determine the presence of a limb length discrepancy) can help establish the diagnosis and determine the level of the anomaly and its severity. If radiography is performed very early, such as shortly after birth, calcification may not be sufficiently advanced, especially in the affected bones, to determine the full extent of the malformation or the true size of the affected bones (see Fig. 48-1, *E*). For this reason it is frequently preferable to wait until 6 to 8 months of age or even later before performing radiography, particularly when no surgery is planned at a young age. In cases in which a toe phalanx transfer is planned, anteroposterior radiography of the toes close to the time of surgery should be performed to choose the most appropriate toe phalanx in width and length for the procedure.⁸⁶ When the patient is very young, significant amounts of these bones are still cartilaginous; therefore portions are not yet visible. This must be taken into account when choosing a toe phalanx, because the actual bone is longer and wider than that measured. Similarly, it may be preferable to repeat earlier radiography or wait until just before surgery to obtain certain hand radiographs to better evaluate the malformation for surgery. When clinical signs warrant, medical imaging (such as a scoliosis series, CT scanning, or MRI) is useful to establish the extent of the malformation in the trunk. In addition, occasionally, psychological evaluation and follow-up support may be an essential component of the treatment plan for certain patients.

TREATMENT OPTIONS

There are many cases of mild undergrowth that require no treatment of any kind. Some mild cases of joint stiffness or flexion contracture can benefit from stretching exercises and/or splinting in occupational therapy. Patients with more severe undergrowth are best left alone in the following circumstances: when the risks or complexity of the possible surgical procedures outweigh the gains, when parental or patient expectations are greater than what can be realistically achieved, when surgery is not desired by the family or patient, in an adult patient who functions well and has become accustomed to the deformity, or when serious health conditions dictate. In most cases, surgery must be tailored to the individual patient's needs and wishes, the deformity, and functional problems.

PREOPERATIVE PLANNING

Surgical treatment can be subdivided into four general categories: web-deepening procedures (most often syndactyly releases), lengthening techniques, joint stabilization operations (usually fusions), and other corrective procedures including tendon transfers or even amputations.

Surgical Plan

The actual choice of procedure depends, at least in part, on the following: the age at presentation; presence of bilaterality; involvement of the feet; severity, number, and size of the digits; presence and degree of clinodactyly; active range of motion at each joint; and presence of joint instability.

When a single digit is shorter, especially the little finger, although no treatment is generally indicated, power grip strength may be decreased.⁶ When multiple digits are significantly shorter than normal, deepening of the web spaces can achieve a relative increase in length and capacity for abduction. This can allow better stability in grasping larger spherical or irregularly shaped objects.⁶ When syndactyly is also present, the indications are even greater.

When multiple digits are more severely involved with a deficient bony structure, but have adequate soft tissue envelopes, toe phalanx bone grafting can be considered,^{5,69,71,86-90} particularly when there is adequate active flexion and extension. Even small flail nubbins may be useful to patients as they grow, such as to manipulate thread. Waiting before deciding the fate of such nubbins and adequate assessment by an occupational therapist are strongly recommended. If they interfere with function, they are best amputated. Amputation can often be combined with web deepening of the central portion of the hand,⁶⁹ achieving a relative lengthening of the remaining brachydactylic digits.

Rare cases of multiple digital brachydactyly can be appropriate for an "on-top-plasty" of one finger stump onto another (usually adjacent) stump.⁹¹ This technique is most useful to reconstruct the first web space components, such as transferring the index stump onto the middle finger stump, thereby creating a longer ulnar component and wider first web.^{6,91} Adequate bony elements and appropriate relative neurovascular pedicle lengths are essential in performing an on-top-plasty (that is, if the metacarpal of the digital stump being transferred is significantly shorter than that of the recipient, one may have to place the recipient joint or joints into flexion), to prevent a permanent flexion contracture.⁶ Distraction lengthening can facilitate some cases of on-top-plasty.⁹¹

If there is sufficient bone volume and length, various types of distraction lengthening^{5,92-99} may be helpful. It is nevertheless important to keep in mind that this option will not provide additional joints or increased motion and may even, in some cases, result in some stiffness of the

functional joints present.^{6,8,99} It is therefore best to reserve this technique for cases with functional loss of prehension and grip rather than for cosmetic reasons,⁹⁴ although some patients may desire surgery, after thoughtful discussion, for appearance only.⁹⁶ In cases of monodactyly or peromelia (that is, adactyly), free neurovascularized toe transfer^{32,71,88,100-102} may be an option to provide pinch and facilitate bimanual tasks.

Position and Marking

The patient is positioned supine, with the involved limb abducted and resting on a hand table. In very small patients, the head and shoulder can rest on the proximalmost part of a sufficiently wide hand table. The rest of the body is then positioned somewhat obliquely away from the hand table toward the opposite-side foot of the main operating table. This allows the hand to extend further on the hand table (see Fig. 47-8 in Chapter 47) to facilitate the surgeon's approach to the hand. When access to the foot or iliac crest is required, this position allows both to be reached. A tourniquet is applied and used intraoperatively on the upper limb, at 200 mm Hg or less in younger and 250 mm Hg or less in older healthy normotensive patients,^{103,104} and on the lower limb between 250 mm Hg or less and 300 mm Hg or less, respectively.¹⁰³ The tourniquet is deflated for 15 minutes or more¹⁰⁴ after 1.5 to 2 hours of inflation.^{103,104} According to Crenshaw,¹⁰³ it is less traumatizing to leave the tourniquet in place for 2 hours, or even a few minutes longer, and then deflate without reinflating it, than to deflate it for 10 minutes and reinflate it for the additional time required. Markings are made according to the technique planned (see the next section on Surgical Technique), and the patient is prepped and draped as usual. Prophylactic antibiotics are not generally used, unless there is a specific indication, such as prophylaxis for free toe phalanx transfer⁸⁶ or long operations such as free neurovascularized toe transfer.

SURGICAL TECHNIQUE

Web-Deepening Procedures

There are two general forms of web deepening: syndactyly releases, which are used between two short fingers that have a degree of syndactyly or between two short fingers that require relative lengthening; and multiple Z-plasties, which are used to deepen the space between a reduced number of fingers to allow a broader grip.

Syndactyly Releases

In cases of moderate brachydactyly or symbrachydactyly, standard syndactyly releases can sometimes be sufficient and beneficial (Fig. 48-9). The age at release is similar to that suggested for standard syndactylies. Some authors suggest treatment of the first web at or before 6 months of age to allow appropriate development of grasp between the thumb and the rest of the hand,¹⁰⁵ because patterns of hand function develop between 6 months and 2 years of age,^{105,106} and thumb opposition develops at approximately 7 months of age.¹⁰⁷ It is also suggested that surgery be undertaken before 1 year of age for any web where a difference in the length of the digits causes tethering.^{105,108} Otherwise, releases should be undertaken after 18 months of age to achieve the best results.¹⁰⁵ I often prefer to wait until a child is 9 to 12 months of age to release the first web, because anesthesia is less risky, surgery is easier, and neurovascular risk and the risk of flap necrosis are lower, as a result of the digital structures at this age being somewhat larger. Unless a release is required at an earlier age, for any of the previously mentioned reasons, I also prefer to perform surgery for the rest of the webs after 3 years of age, when collaboration with postoperative therapy—that is, the ease of pulling on compressive gloves, and keeping on silicone

Fig. 48-9 Syndactyly releases in the treatment of symbrachydactyly. **A**, Left hand before surgery. **B**, Left hand after combined first and fourth web syndactyly release, which were performed together, because eventual amputation of the third severely hypoplastic ray was planned, permitting the correction of the web between the second and fourth digits to be performed at that time. **C**, Left hand after amputation of the third ray and completion of all syndactyly releases.

and splints—is much easier. All necessary releases should nevertheless be completed by school age and planned accordingly. If all four web spaces require release, the first and third should be done simultaneously¹⁰⁵ at an early enough age to allow appropriate cortical integration of the thumb. The second and fourth webs can then be operated on together,¹⁰⁵ after the scars from the first operation have sufficiently matured and softened to allow reintervention. If only the second through fourth web spaces require release, the second and fourth should be done together first, followed by the third.¹⁰ Most authors suggest not operating on both sides of the same digit at the same sitting,¹⁰⁵ to avoid jeopardizing the vascular supply to the digit.¹⁰ A technique involving three adjacent web spaces has nevertheless been described.¹⁰

When several adjacent web spaces require correction, it is important to plan as if each digit will end up with only one arterial pedicle. This approach is important, because the division of the common digital artery into proper digital arteries may be more distal than usual^{4,69} and because relative lengthening of short digits often requires ligation of one of the two digital arteries, even if their bifurcation is at the usual level. During surgery, the two nonadjacent web spaces are explored, once the syndactyly release incisions have been made, to ensure that none of the proper digital arteries is absent. The proper digital artery that one wishes to sacrifice in each space is clamped, and the tourniquet deflated to verify the blood supply to each digit. When this is done, one must ensure that, should one of the two arteries require ligation in the intervening web space, the vascular supply of the corresponding digit is intact on its opposite side.

Because these digits are shorter than normal, I use two relatively short, proximally based triangular flaps, one based on the palmar side and the other on the dorsal side of the syndactyly, to line the depth of the web³² (Fig. 48-10). This decreases the quantity of the skin graft necessary on the adjacent digital bases compared with a single proximally based rectangular flap used to line the depth of the web. There are authors who still prefer the use of a wide dorsal flap for their syndactyly releases to prevent the development of a narrow V-shaped commissure.¹⁰⁵ When used, the two triangular flaps are drawn slightly offset in a radioulnar direction, one in relation to the other, and long enough so that their tips cross over somewhat. Full-thickness skin grafts are used to close the remaining open wounds to limit contraction. Split-thickness grafts are avoided, because they often result in recurrence of the syndactyly. The donor site for a smaller graft can be the proximal ulnar forearm or the palmar non-hair-bearing distal forearm (harvested in a lon-

Fig. 48-10 Syndactyly release for symbrachydactyly. **A**, Left hand, dorsal aspect, before surgery. **B**, Left hand, palmar aspect, before surgery. **C**, Left hand, dorsal aspect, at completion of surgery. Note the use of relatively short triangular proximally based dorsal flaps to help line the depth of each web, the tips of which overlap side to side with the corresponding palmar short triangular proximally based flaps. **D**, Left hand, palmar aspect, at completion of surgery.

gitudinal direction to avoid the social stigma associated with transverse wrist scars), with a very good color match in most patients. For larger grafts, the infrequently hair-bearing lateral lower abdominal skin can be used. Despite larger quantities of skin, this lateral lower abdominal skin is not as good of a color match for the hand. The inguinal skin is not only a poor color match, becoming darker in more pigmented skin types,¹⁰ but also often grows hair after puberty. The Sherif technique,¹⁰⁹ which usually does not require skin grafts when used for simple syndactyly release, is indicated only when a single web requires treatment. Transverse skin laxity on the dorsum of the hand rarely allows the harvesting of several adjacent Sherif flaps, in addition to leaving conspicuous longitudinal scars.

Multiple Z-plasties

In cases where the digital nubbins (which replace the index, middle, and ring fingers), require amputation, multiple serial Z-plasties^{69,110} should be considered to deepen the space between the hypoplastic thumb and the little finger (Fig. 48-11). This should be done before the child is of school age, and when collaboration with postoperative therapy is sufficient.

At surgery the incisions are drawn, but the flaps are not all incised at once. Starting at one end of the planned web, the first pair of flaps is incised, interposed, and tacked before moving on to the next set of flaps, and so on. This avoids errors in flap design, because when one moves toward the depth of the web, the flap angles change from what was originally drawn. It may be

Fig. 48-11 Multiple Z-plasties to deepen the web between the only two useful border digits in symbrachydactyly of a patient's left hand. **A**, Dorsal preoperative appearance. **B**, Web preoperative appearance. **C**, Dorsal appearance at the end of surgery; amputation of useless vestigial nubbins was undertaken simultaneously. **D**, Web at the end of surgery; interdigitating flaps decrease the risks of web contracture formation.

useful to shorten and contour the distal ends of the hypoplastic metacarpals present in the depth of the new interdigital space and/or excise any extremely hypoplastic rays that cannot benefit from reconstruction.¹¹⁰ In some cases shortening the metacarpals may be contraindicated, because they provide increased grasp stability, and should therefore not be performed. Thorough preoperative occupational therapy evaluation can identify which patients should and which should not have their metacarpals shortened.

Bone-Lengthening Techniques

Lengthening techniques include free toe phalanx transfer, on-top-plasty, ray transposition, distraction, and free neurovascularized toe transfer.

Free Toe Phalanx Transfer

If the cutaneous sleeve is of sufficient dimensions, an appropriate reconstructive method (Fig. 48-12) includes the transfer of a free, nonvascularized toe phalanx. The toe phalanx allows a better long-term survival rate, approaching 100%, unlike conventional bone grafts from the iliac crest or fibula, which resorb.³² To have a chance of surviving, the bone graft must include the periosteum.*

Fig. 48-12 Free toe phalanx transfer to the index finger in symbrachydactyly. **A**, Preoperative posteroanterior radiograph of the left hand. **B**, Preoperative appearance of the left hand. The index fingertip is unstable for pinch. **C**, Planned incision for the free toe phalanx transfer to the monophalangeal index finger to stabilize the flail tip. **D**, Anteroposterior radiograph of the left foot in which the fourth toe proximal phalanx will be harvested. **E**, Planned incision for harvesting the fourth toe proximal phalanx. **F**, The fourth toe proximal phalanx has been removed; the extensor tendon is retracted to the lateral side and the head of the metacarpal is visible in the depth of the wound. **G**, The fourth toe proximal phalanx has been harvested including the periosteum, proximal collateral ligaments, the plantar plate, and the proximal joint capsule. Unfortunately, despite precise measurements on the preoperative radiographs, the width and length of the phalanx were excessive when attempting its transfer to the index finger and required reduction. During the reduction procedure, the periosteum was kept pedicled to cover the sites of bony reduction. **H**, The right iliac crest was prepared for harvesting a bone graft to fill the donor defect in the toe. (**NOTE**: X marks the anterosuperior iliac spine. The incision is planned for just below the iliac crest to prevent a scar in the area subjected to the most friction from clothing, and posterior to the X to avoid branches of the lateral femoral cutaneous nerve.) **I**, Bone of adequate width and length for the donor defect in the toe, is harvested from the iliac crest with a trepan.

Continued

Fig. 48-12, cont'd **J**, The iliac crest bone graft is adjusted to fit the toe phalanx donor site, and is pinned with a longitudinal K-wire before the wound is closed. **K**, Anteroposterior radiograph of the left foot after iliac crest bone grafting of the toe phalanx donor site. **L**, Appearance of the index finger after transfixion pinning of the reduced toe phalanx into the distal soft tissue sleeve. Chondrodesis between the distal end of the index proximal phalanx and base of the toe phalanx was undertaken, as was suturing of the toe phalanx ligament to the perichondrium on the radial side of the index proximal phalanx. There was not enough space to do the same on the ulnar side. **M**, Posteroanterior radiograph of the left hand with the pinned toe phalanx in place at the distal end of the index finger. **N**, Left foot 2 months after surgery. No toe shortening, instability, or stiffness is present at the metatarsophalangeal joint at 2 months or 6½ months after surgery. **O**, Left hand 2 months after surgery. Stability is improved in the previously flail index fingertip and is now used in pinch.

Most authors recommend using the fourth or possibly the third toe,⁹³ and keeping the second toes and possibly even the third toes, for possible future free neurovascularized transfer. The fifth toe is avoided because of potential problems with donor site instability,⁸⁶ particularly when the donor site is not bone grafted. The proximal⁸⁹ or middle⁸⁶ phalanx can be used. An anteroposterior radiograph of the toes permits rough measurements to be obtained,⁸⁶ helping to determine which phalanx would be the most appropriate.

This technique is most appropriate when there is good active flexion and extension of the nubbin, and when pinch or global hand function will improve significantly as a result of this additional stable digit.⁷¹ When grafting a monophalangeal digit in which functional tendons are present and can mobilize the proximal phalanx, the transfer is even more functional (J. Upton III, personal communication, 2006).

The recommended age at surgery varies somewhat. Buck-Gramcko⁸⁷ noted that after surgery between 7 and 18 months of age, the growth plates remain open in the highest percentage of grafts (65.7%) compared with older patients, whereas between 1.5 and 4 years the average growth is the greatest (3.5 mm) compared with either the younger or older age groups. In the

series undertaken by Cavallo et al,⁸⁶ average growth was also somewhat better in the middle age group (that is, 18 months to 4 years), although it was more modest, with an average of 0.2 mm of growth, whereas the younger and older age groups each had a net average resorption of 0.4 and 0.1 mm, respectively, at follow-up. Radocha et al⁸⁹ obtained physeal openness in toe phalangeal grafts of 94% in those operated on before 1 year of age and 71% for those operated on between 1 and 2 years of age, with a severe drop-off thereafter. They measured growth to be, on average, 1.0 mm per year for both of these groups and less so in the older children. Unglaub et al⁹⁰ noted the least resorption (9%) and the most growth (73%) in the youngest age group operated on between the ages of 6 and 18 months compared with the older patients. These findings did not correlate with the presence of open growth plates at follow-up examination (on average, 3.5 years after surgery), which were 73% in the youngest age group, 90% in the children between the ages of 18 months and 4 years, and 71% in the older patients.⁹⁰ Dobyns⁵ suggests that surgery be performed before 18 months of age, Kay and McCombe⁷¹ recommend surgery only for patients 15 months of age or younger, whereas Peimer and Alexander⁸⁸ suggest that this operation be performed before 1 year of age. Of note, true growth is a difficult parameter to evaluate in a growing child. Its measurement is subject to many variables, including variations in radiographic magnification (dependent on the distance between the bone and the radiographic plate), the increasing degree of bone calcification over time, and the growth of the bone relative to the bones of the normal hand, the donor foot, and the other bones of the affected hand.

In the hand, a longitudinal palmar,⁷¹ dorsal,^{71,86,89} lateral (J. Upton III, personal communication, 2006), dorsal zigzag,^{6,87} dorsal curved,⁶ or dorsal V-Y incision⁸⁸ is made. In multiple proximal digit grafting, a transverse dorsal distal metacarpal incision (J. Upton III, personal communication, 2006) can be used instead. The soft tissue envelope is gently handled throughout the operation, and some fat and fibrous tissue is removed to accommodate the planned phalanx transfer.^{71,87,88} The skin at the tip of the soft tissue sleeve must remain intact and well vascularized.⁶ The size of the available space can be assessed by inspection, and this, along with measurements on the preoperative radiographs of the toes, can help determine which phalanx is the most appropriate for the transfer.⁸⁶ It is important to remember that significant portions of the toe phalanx are cartilaginous at this age and therefore not visible on the radiographs. Cavallo et al⁸⁶ also noted that complete harvest of the second phalanx seems more resistant (less resorption [3 mm versus 6 mm]) and shows more growth (2 mm versus 1 mm) than subtotal harvest of the first phalanx on follow-up examination after transfer. It is therefore probable that completely harvesting a phalanx of the appropriate size, rather than shortening one that is too long, will give better results.

The selected toe phalanx is approached either through a dorsal longitudinal,^{5,86,89} zigzag,^{71,87} S-shape,⁶ curvilinear,⁶ or midlateral incision (J. Upton III, personal communication, 2006). The extensor tendon is retracted to one side,^{6,87} or split^{5,6,70,71,89} and elevated from the underlying periosteum. The flexor sheath is released to free the flexor tendon from the overlying bone (J. Upton III, personal communication, 2006).⁷¹ To ensure the best growth plate survival and subsequent growth, the chosen phalanx is harvested including all its periosteum,* capsular attachments,^{5,6,71} proximal collateral ligaments,^{5,6,32,87,89} and in the case of some investigators, plantar plate.† Occasionally, if joint reconstruction is indicated, the head of the proximal phalanx, along with the proximal interphalangeal joint and the entire second phalanx, can be harvested.⁷¹ The donor defect can be treated in several different ways. Some leave it to retract, after repair of the extensor tendon, if split, and after closure of the skin.^{6,86} Others stabilize the defect with a longitudinal K-wire.^{71,89} Some investigators fill the donor defect by suturing the extensor, flexor, and what is left of the collateral ligaments together to serve as a spacer.^{87,111} Finally, others graft the site with the use of a cylindrical piece of iliac crest bone, capped with epiphyseal cartilage, which

*References 5, 6, 10, 32, 69, 71, 86, 87, 89.

†References 5, 6, 32, 71, 87, 89.

is placed proximally and immobilized with a K-wire (J. Upton III, personal communication, 2006).⁷¹

In the hand there is a coalescence of fibrous tissue, including attachment of the flexor and extensor tendons into a “cap.” Some leave the cap intact, suturing the phalanx transfer to its distal surface.⁸⁶ Others prefer to either divide this cap transversely into palmar and dorsal components to reconstruct the flexor and extensor tendons,⁸⁷ sagittally to reconstruct the collateral ligaments,⁸⁹ or in a cruciate fashion into palmar, dorsal, radial, and ulnar components.⁷¹ When reconstructing the collateral ligaments, the radial and ulnar components are used, whereas the palmar and dorsal components are used for the tendons. Because of the relatively greater strength and excursion of the flexor tendon, it is best to leave the flexor tendon relatively longer than the extensor tendon when dividing the cap to prevent a flexion contracture. If there is a sufficient amount of bone in the digital proximal phalanx, the tendons present are already inserted into the base of this phalanx.⁷¹ In this case, the distal end of the digital proximal phalanx and the base of the toe phalanx transfer only require preparation for either chondrodesis⁷¹ or bone-to-bone fusion while preserving the epiphysis.⁸⁷

The toe phalangeal transfer is inserted into the recipient pocket in the hand, ensuring that tension on the skin does not cause ischemia.⁶ The transfer is immobilized with a K-wire,^{5,71,86-89} while minimizing trauma and heat to avoid injury to the epiphysis.⁷¹ The ligaments can be repaired,^{71,87-89} while the extensor tendon is reattached to the base of the toe phalanx^{87,89} or to the dorsal capsule of the toe phalanx transfer,⁷¹ when indicated. The flexor tendon, where appropriate, is either attached to the palmar base of the toe phalanx transfer, leaving the palmar plate free to attach through adhesions⁸⁷ or to the palmar plate itself.^{71,89} Skin closure may be done first, but if there is tension, a Z-plasty,⁷¹ local rotation flap,^{87,89} or transposition flap⁸⁷ may also be necessary.

On-Top-Plasty

On-top-plasty^{6,91} is rarely used because of the risks of circulatory compromise in the transferred segment or a flexion contracture of the transferred segment as a result of the positioning necessary to reduce the tension on its neurovascular pedicle. It should be considered only in selected cases when these risks are low. On-top-plasty is most often indicated to reconstruct the first web space components such as transferring the index stump onto the middle finger stump, thereby creating a longer ulnar component and wider first web,⁶ or onto the first ray to reconstruct a hypoplastic thumb.^{5,91} An example of the former is the presence of a second metacarpal, with or without a small, actively mobile portion of the proximal phalanx, too short and too close to the thumb for use in functional pinch, adjacent to a relatively shorter third metacarpal. The second ray is dissected as a neurovascularized pedicled finger ray, similar to the manner undertaken in pollicization, and transferred onto the third metacarpal base. The base of the second metacarpal may be left behind, if its inclusion would result in excessive neurovascular tension. The first web is thereby deepened, the third ray is lengthened, and the longer digit is in a better position for pinch with the thumb. Although there is no recommended age for this procedure in the literature, there may be some benefit in waiting until the patient is less prone to vasospasm, which is after 1 year of age or more than 10 kg in weight (J. Dubois, personal communication, 2006). Occasionally it may be helpful to distract an otherwise useless segment with the aim of transposing it as an on-top-plasty to a more useful position.⁹¹

Ray Transposition

Another ray transposition, although not a true on-top-plasty, has been described by Kay and McCombe.⁷¹ In a case of monodactyly, the thumb, with no mobility at any joint, was transposed to the ulnar side of the hand as a neurovascular pedicled transfer. This was done in preparation for a free neurovascularized transfer of the mobile second toe to the thumb position to improve grasp. A similar technique, but employing a microsurgical free transfer, can be used for transfer-

ring an otherwise useless radial finger vestige into an ulnar position or as an on-top-plasty onto an ulnar metacarpal remnant.^{5,32}

Distraction

There are three variations on distraction: distraction with immediate bone grafting, gradual distraction with secondary bone grafting, and gradual distraction with callotasis bone formation. Distraction with immediate bone grafting permits more conservative lengthening in a single stage. Gradual distraction with secondary bone grafting allows greater lengthening but requires bone grafting at completion. Gradual distraction and callotasis bone formation has the advantage of achieving greater lengthening without necessitating bone grafting in successful cases, but it requires additional months of immobilization with a risk of decreased resistance to stress.⁹⁹

Distraction With Immediate Bone Grafting

Distraction with immediate bone grafting results in limited lengthening of certain long bones, but only if there is enough bone stock to allow for osteotomy, handling, fixation, and bony consolidation. The age at surgery can vary from preschool age, recommended for its positive psychological benefit, to when a patient is old enough to decide for himself or herself.⁹ Although there is no clear recommended age for this procedure, the older the patient, the more likely it is that the previously mentioned preoperative requirements are met. In a report by Saito et al,⁹⁸ two patients were 13 years of age at the time the procedure was performed and the age of the third patient was not mentioned.

Joint contractures are a risk with any type of distraction lengthening.^{6,8} One-stage lengthening with bone grafting is rarely advocated in the phalanges, for fear of upsetting the delicate balance between the flexors and extensors; therefore one-stage lengthening is mostly used to lengthen metacarpals.⁵ Although most authors^{8,39} use a dorsal approach for metacarpal lengthening, Saito et al⁹⁸ described a palmar approach. In addition to a transverse osteotomy,¹¹² various other bone cuts have been described to improve stability, including a step cut,¹¹³ a V shape,^{39,98} a chevron shape,¹¹⁴ and a dowel shape, which is a piece of iliac crest in which holes are reamed to support the two ends of the lengthened metacarpal.¹¹⁵ Soft tissue release, muscle slide, and reconstruction of the intermetacarpal ligament are often necessary to achieve maximum lengthening.^{6,39,98,112,114} Reattachment of the interosseous muscles to the bone is advocated by some after muscle slide.^{6,39} An iliac crest bone graft is often used,^{6,39,98,114,115} although fibula and other sources of bone grafts have been advocated.⁶ Elongation with the use of this technique is between 5 and 15 mm,^{9,98,116} and fixation is achieved by means of intraosseous wires,⁹ K-wires,^{5,9,39} plates and screws,^{5,39} a K-wire-fixed distraction device,¹¹³ or an external fixator.⁸

Gradual Distraction With Secondary Bone Grafting or Callotasis Bone Formation

Distraction lengthening generally necessitates sufficient bone to permit stable insertion of the fixation device in addition to sufficient bone necessary for the osteotomy, handling, and bony consolidation. These details therefore affect the age at which distraction is undertaken. Some authors state that distraction should be postponed until 1 or 2 years of age.¹¹⁶ Others believe that because of the size of most distraction devices, distraction is impractical before 2 years of age, but should be completed by the age at which school begins⁶ or even between 2 and 4 years of age.³⁹ Others recommend, for brachymetacarpia at least, waiting until the patient is 8 to 14 years of age¹¹⁶ or in the range of 10 to 15 years of age because of excellent callus formation, consolidation, and near closure of the growth plates, simplifying estimation of necessary lengthening; in addition, patient motivation is higher in this older age group and patients can adequately care for the fixator by themselves.⁹⁵

Despite the varying opinions, the age at which surgery has been performed varies widely in the literature. Arslan's patients ranged from 10 to 14 years of age,⁹² Kato et al's⁹⁵ from 10 to

19 years, Belusa's patient was 16 years of age,⁹³ the patients of Pensler et al⁹⁷ were from 2.5 to 7 years, those of Dhalla et al⁹⁴ from 2 to 16 years, and of Matsuno et al⁹⁶ from 1 to 13 years of age. Dhalla et al⁹⁴ and Matsuno et al⁹⁶ used variations in technique that permitted very small bones to be addressed, making it possible to treat some very young patients. Nevertheless, this technique is usually recommended for larger bones. Both Dobyns⁵ and Flatt⁶ suggested limiting its use to bones of at least 3 cm in length. Double pin fixation on either side of the osteotomy is generally suggested to maintain alignment during distraction.⁸ Using this technique, Dhalla et al⁹⁴ recommended a minimum bone length of 2.3 cm but as little as 1 cm using a modification with a single pin on either side of the osteotomy along with a longitudinal intramedullary K-wire to provide stability. Even smaller bones, as short as 3 mm, have been successfully lengthened by Matsuno et al⁹⁶ using an apparatus that could fix transverse K-wires—placed across joints where necessary—along with a longitudinal intramedullary K-wire to increase stability. Some authors use a longitudinal intramedullary wire, during metacarpal lengthening, through the metacarpal and phalanges to maintain alignment, even with larger bones.^{39,116} Others use longitudinal K-wires for a different reason, pinning joints distal to the area of distraction to avoid progressive flexion contractures common to lengthening.^{6,88,116} External splinting has also been used for this reason.⁶

Although lengthening by gradual distraction has been used for both phalanges and metacarpals, only 23 of the 75 bones elongated by a number of different investigators were phalanges.⁹²⁻⁹⁷ It is important to note that this technique does not create new joints, thus excessive elongation can result in a stiff,^{8,99} thin,⁹⁹ or even contracted⁸ digit. Some authors therefore believe that the best candidates for phalangeal distraction are those who have significant shortening along with an associated deformity, such as angulation, that requires correction,⁸ or occasionally, to create some form of pinch where it is absent. Both single and multiple digits can be treated,⁶ even simultaneously in the same hand.^{88,95-97} As previously noted, it may be useful to consider distracting an otherwise useless segment with the aim of transposing it as an on-top-plasty,⁹¹ usually on either side of the first web.^{5,91}

The distraction technique involves access through a longitudinal incision usually on the dorsum of the hand (Fig. 48-13) for the metacarpals,^{8,39,94,95,116} which is slightly offset in relation to the axis of the digit.^{95,116} An osteotomy is made, midway between sets of double (or single⁹⁴) half-pins^{8,95} or K-wires inserted to stabilize the proximal and distal fragments.^{5,6,39,116} Some prefer to make the osteotomy in the metaphysis,³⁹ whereas others prefer the middiaphyseal region⁹⁴ or even through a joint system.⁵ The cut is made either through both periosteum and full-thickness bone, which usually requires bone grafting at the end of distraction^{5,6,39,99,116} or preserving the periosteum.^{39,94,95,97} A step-cut osteotomy in the diaphysis can occasionally allow distraction without necessitating either callotaxis bone formation or bone grafting, permitting consolidation between the surfaces of the bone in contact at the end of distraction (see Fig. 48-13).

As previously mentioned, a longitudinal intramedullary K-wire can be inserted in the metacarpal and phalanges to maintain alignment, as well as fixation of the proximal and distal fragments.¹¹⁶ Various types of frames exist, including K-wires mounted in a half-circular frame,¹¹⁷ K-wires mounted in a bilateral longitudinal frame,^{5,39,116,118} and half-pins mounted in a unilateral longitudinal frame.^{94,97} The Ilizarov method, which also includes the preservation of the medullary cavity, is not practical in the small bones of the hand.³⁹ Multilayer closure is undertaken, a dressing applied, and distraction begun in the days after surgery, according to the surgeon's protocol. In cases where there are problems with consolidation^{91,95} or when consolidation is not expected at the end of distraction, the gap is grafted with an iliac bone graft,^{6,39,95,99} toe phalanx,^{6,39} fibula, bone from a vestigial digit, or other source.^{6,39,99,116} Most patients (71 out of a combined 75 patients) go on to form bone through callotaxis, healing without the need for secondary bone grafting.⁹²⁻⁹⁷

Two sets of half-pins were used on either side of the osteotomy for fixation. **D**, Right hand posteroanterior radiograph during distraction lengthening. Some deformity into flexion occurred during distraction, necessitating realignment in the operating room. **E**, Right hand during distraction lengthening.

Free Neurovascularized Toe Transfer

Finally, there is the possibility for free neurovascularized toe transfers to the hand (Fig. 48-14). Some authors suggest that this procedure be performed at 2 years of age.¹¹⁹ Others suggest that surgery be performed at an even younger age, because patterns of hand function are generally established between the ages of 6 months and 2 years,¹⁰⁶ with thumb opposition beginning at approximately 7 months of age.¹⁰⁷ Lister¹⁰² recommends that in unilateral deformities, the surgery be completed before 18 months of age, but mentions that it can be undertaken as early as 6 months of age. Nevertheless, some prefer to wait until after the patient reaches 4 or 5 years of age⁸⁸ before undertaking such transfers. In bilateral deformities, the transfer will probably be used regardless of the age at which surgery is undertaken.^{101,102}

Fig. 48-14 Free neurovascular transfer of a second toe to the ulnar side of the hand for monodactylic aphalangic symbrachydactyly. **A**, Preoperative anteroposterior radiograph of the palmar surface of the right hand. **B**, The palmar surface of the right hand before surgery. **C**, The palmar surface of the right hand during surgery, after web deepening and preparation of the recipient site on the ulnar side, including the identification of appropriate vessels, nerves, and tendons. **D**, Preparation of the left second toe for free neurovascularized transfer. **E**, Appearance of the foot donor site at the end of surgery after closure of the defect. **F**, Appearance of the well-vascularized transferred toe in the dressing at the end of surgery. **G**, Use of the transfer 3 years postoperatively.

The second toe (or toes) in children are usually used to minimize the donor defect in the foot.^{71,101,102,120} Rarely, a second and third toe^{32,121} en bloc transfer or even a combined third and fourth toe transplantation¹²¹ have been undertaken. Others consider these combined toe transfer procedures too disfiguring¹⁰⁰ and have found them to cause, at least in adults, more foot problems than a single first or second toe transfer.¹²⁰ Rarely, other types of transfers, such as a wraparound free flap or a partial toe transfer, may be indicated in select cases in the older child.⁷¹ Toe transfers are generally not a solution for replacing one, two, or even three missing fingers, because they do not resemble or function like normal digits and their range of motion is frequently limited.^{32,71,101} There are, nevertheless, cases in which reconstruction using toe transfers improves prehension patterns and appearance by giving the hand a total of two or three “fingers.”^{32,100,119,121} This is achieved by transferring a single second toe or two second toes, or performing a double toe transfer, to a hand that has a single finger or no digits at all.

Although toe transfers are most often used to replace a missing thumb,^{71,100,101} in *syndactyly*, the thumb is usually the last digit absent. If this thumb is short, unstable, or poorly oriented, the previously mentioned lengthening and other standard stabilization and reconstructive procedures are indicated. These more classical methods may also be used to provide an adequate ulnar post against which a stable, well-positioned thumb is able to grasp. Otherwise, toe transfers can replace an absent ulnar post and/or thumb. The best results are obtained when the metacarpophalangeal joint of the finger (or fingers) is present⁷¹ and, in the thumb, when the carpometacarpal joint is stable and mobile.^{71,100} If the metacarpophalangeal joints are absent or unusable, a chondrodesis or arthrodesis between the proximal phalanx of the transfer and the hand metacarpal is generally more stable and allows better orientation of the digit.⁷¹ If the thumb basal joint is present, and two toe transfers are planned, some authors suggest that one toe be positioned in the thumb location and the other on the third or fourth ray.⁷¹

The more proximal the digital absence, the more likely it is that necessary recipient structures are inadequate.⁷¹ It is therefore essential to explore the recipient structures before harvesting the toe (or toes) and to determine the amount of bony framework (that is, whether or not the metatarsophalangeal joint should be included), length of tendons, neurovascular pedicles, and skin necessary for the intended reconstruction.¹²⁰ If the thumb basal joint is inadequate, some authors suggest that two relatively short toe transfers be placed, facing each other, close enough to permit the tips to touch in maximum flexion.^{71,100} This allows grasping of small objects, which is preferred to the ability to hold large objects.^{71,100} Others contend that, in unilateral cases, fine manipulation will be preferentially undertaken with the normal hand, so a strong grasp with a wide span should be reconstructed in the affected hand.¹⁰¹ Some have even undertaken the reconstruction of the basal joint by including the metatarsophalangeal joint in the free neurovascularized transfer.¹²² When the basal joint of the thumb is normal, the position is adjusted to permit both tip-to-tip and tip-to-side pinch.¹⁰⁰

Büchler³² has suggested some rather aggressive procedures in cases of *peromelic syndactyly* (that is, the absence of all digits at the metacarpal level). These include transferring one second toe to the thumb position and a double second and third toe to the third and fourth ray positions. He has also reported transferring the index finger from the normal hand to the third metacarpal and a double toe transfer to the fourth and fifth rays in a single sitting, followed 6 months later by a single toe transfer to the thumb position.³² Others prefer not to transfer more than two toes, and thus suggest two-toe hands in *peromelic* cases, or three-digit hands in *monodactylic* hands (including two toes and the thumb present), augmenting the thumb ray, if necessary, with a free phalangeal transfer.¹⁰⁰ If there is a clinical indication for lower limb amputation, transplantation of any useful toes should be considered.¹²³ Details of free neurovascularized toe transfer can be found in Chapter 51.

Joint Stabilization Operations

Rarely, unstable joints may be appropriate for formal ligament reconstructions³² (see Chapter 44). Many ligament reconstructions are best treated with joint fusion,³² particularly in cases where hypoplastic digits have too much laxity and underdevelopment of the supporting structures to achieve sufficient stability with other methods.

Other Corrective Procedures

Other corrective procedures include various techniques for improving function and/or appearance. Some examples are pronation osteotomy of the first metacarpal³² to improve the position of the digit for grasp, and tendon transfers to increase adduction or palmar abduction of the thumb.³² Amputation is appropriate in certain cases, such as when the following is present: vestigial nubbins⁶ that provide no increased function, are in the way, and are too small to accommodate toe phalanx transfers (see Fig. 48-11); portions of nonfunctional digits (see Fig. 48-9), parts of which can be used elsewhere⁸⁸; or a flail single hypoplastic ray in a normal or near-normal hand⁸ that interferes with function.

POSTOPERATIVE CARE

At the time of surgery, it is possible to increase postoperative comfort by using a digital or distal regional bloc, such as a median nerve or ulnar nerve at the wrist, with a long-acting agent such as bupivacaine. A well-padded dressing avoids pressure points. The dressing must not be too tight, which could cause postoperative compression and go unnoticed when a regional block is used, although this is less likely to occur than with a more proximal regional block. When the dressing is being applied, it is important to take into account postoperative swelling, which may be substantial if the total tourniquet time is more than 2 hours or if the surgery is extensive. Postoperatively, most upper limb procedures benefit from elevation to minimize edema. To achieve this, suspension can be used (see Chapter 47), and it is usually continued for approximately 1 to 2 weeks. It may be prolonged for procedures that are more extensive or if edema is pronounced. Subsequently the end of the sleeve is tied over the opposite shoulder to the back portion of the attachment around the chest, elevating the hand to the shoulder level. This arrangement is kept under the patient's shirt to help keep the dressing clean and intact.

After the appropriate duration of immobilization, occupational therapy begins. As already specified in Chapter 47 this includes, as required, splinting, scar massages, use of topical silicone to help control hypertrophic scars, compressive gloves (as used in burn scar treatment), exercises, and so on. Not all patients tolerate topical silicone, and some develop an eczema-like rash. In my experience, most patients will tolerate either shorter periods of topical silicone use, such as a few hours per day, or changing to one of the other products that are available. Before the use of topical silicone is abandoned completely, several different types should be tried, because the advantages far outweigh the associated problems. The patients are followed until the scars have matured, which may take 1 to 2 years and sometimes longer. Subsequently the patients are followed for variable amounts of time in the outpatient clinic, depending on the initial malformation, type of reconstruction, results, and the patient's and/or family's understanding of concerns that require repeat consultation. Patients are then asked to return if any problems or concerns arise.

Web-Deepening Procedures

Syndactyly Releases

For syndactyly releases in younger children, a well-padded plaster “sugar-tong” splint (see Fig. 47-19) or, in older patients, a palmar plaster splint, can be used. The hand is positioned in these splints with the wrist in neutral or slight extension and maintained for a period of approximately 1 week. The cast is then removed and the dressing is changed to avoid maceration. Subsequently, if the digits are short enough to be completely immobilized in a generous, well-padded, and adequately wrapped dressing, this is continued for another week or two with twice-weekly dressing changes. Otherwise it may be preferable to reapply a well-padded dressing and reimmobilize the hand in the same plaster sugar tong splint, a palmar plaster splint, or a thermoplastic splint for another week or two, again with twice-weekly dressing changes. After a total of 2 to 3 weeks of immobilization, a well-padded dressing should be changed regularly, keeping the hand protected (that is, in some children, this may mean continuing to keep the hand elevated and under the shirt), until healing is complete.

Multiple Z-plasties

Soft tissue surgery alone, without grafts, often benefits from a well-padded dressing for a total of 7 to 10 days. The dressing is usually changed after 1 week and the wounds are assessed. Afterward, daily dressing changes can be started. Immobilization in a plaster splint for comfort and to protect the incisions, especially in young children, may be useful in some cases.

Bone-Lengthening Techniques

Free Toe Phalanx Transfer

Bone-grafted toe phalanx transfer donor feet necessitate 4 to 6 weeks of K-wire immobilization of the operated toe^{71,89} in a non-weight-bearing posterior plaster splint, with the ankle immobilized in neutral position (that is, 90 degrees). Elevation of the foot to heart level reduces edema, especially in the first 2 or more weeks. Otherwise, if the donor defect is only closed by attaching the tendons and collateral ligaments together, a soft dressing and elastic bandage are applied, allowing the child to walk within 3 or 4 days,⁸⁷ keeping the foot elevated as much as possible the rest of the time. Cavallo et al,⁸⁶ who did not attempt to fill the donor defect, did not limit ambulation at all. For the hand, in these same patients, a well-padded plaster sugar-tong splint (see Fig. 47-19) can be used for immobilization. The K-wire and the cast are continued for 3 to 8 weeks total, depending on the author and details of the procedure.^{6,71,86,87,89}

On-Top-Plasty and Ray Transposition

In on-top-plasty and ray transposition in younger children, a well-padded plaster sugar-tong splint (see Fig. 47-19) can be similarly used for a period of approximately 3 to 4 weeks or more to allow consolidation of the bone and healing of any musculotendinous procedures. Thereafter, splinting may be required for variable amounts of time, depending on the procedure.

Distraction

Distraction With Immediate Bone Grafting

Length and type of immobilization depend on the method of fixation. For cases of distraction and immediate bone grafting immobilized with K-wires, the hand is placed in a short arm cast⁹⁸ or, in younger patients, in a well-padded plaster sugar tong splint, with the metacarpophalangeal

joints in moderate flexion and the wrist in slight flexion.⁹⁸ When the cast is changed, the wrist is brought into slight extension and the cast is worn for 5 to 6 weeks.⁹⁸ The K-wires are removed at 8 weeks, once consolidation is confirmed radiologically.⁹⁸ With the use of a plate and screws, immobilization can be shorter.

Gradual Distraction With Secondary Bone Grafting or Callotasis Bone Formation

In cases of gradual distraction lengthening, with or without secondary bone grafting, a soft dressing is applied, especially in small children,⁵ with or without a plaster splint,¹¹⁶ for the first week or two until the skin has healed. Subsequently some authors immobilize the hand in a plaster and/or thermoplastic splint for various lengths of time during distraction.^{94,99,116} Others have the patient begin range-of-motion exercises,⁹⁴ whereas still others encourage use of the hand in daily activities, even in cases of callotasis bone formation.⁹⁵ Daily pin care is recommended, beginning within a few days of the surgery.^{94,99}

The beginning of distraction is based on whether or not bone grafting is intended but mostly according to each surgeon's personal protocol. Some authors begin distraction within the first few days,^{5,6,97,99} whereas others begin between days 4 and 7,^{8,39,92,95} or even as late as 10 days postoperatively, with some maintaining compression at the osteotomy site before distraction.⁹⁴ If callotasis bone lengthening is intended, some suggest waiting for the appearance of some callus before beginning distraction.⁵ The rate of distraction also varies according to the author from 0.25 to 1.0 mm per day,* in increments of 2 to 4 times per day.†

During distraction, regular radiography and follow-up are initiated, anywhere from twice a week to once every 2 weeks,^{94,95} to ensure progress according to plan. The distraction rate is reduced if there is pain or extreme soft tissue tension.^{99,116} Adjustments in rate are also made according to bone appearance in cases of callotasis bone formation,^{94,95} often necessitating progression with smaller increments.¹²⁴ Distraction is continued until the desired length is achieved. Average distraction length varies from 25 to 70 mm in cases where the periosteum is transected and secondary bone grafting intended,^{5,6} and 10 to 30 mm or more when the periosteum is kept intact, allowing subsequent consolidation of bone callotasis to occur.^{8,88,93-97} The average time for distraction varies from 1 to 3 months.‡ In cases of callotasis bone formation, some authors describe bringing the patient to the operating room at the end of distraction if the skeletal position is not adequate to manipulate the bone regenerate and correct the apparatus position before allowing consolidation.⁹⁷

In cases of secondary bone grafting after distraction lengthening, immobilization is continued for 3 to 4 weeks if the stabilization of the graft is not rigid.⁹⁹ Some immobilize the hand in a splint and keep the K-wires for as long as 6 to 8 weeks when allograft metatarsal bone is used, and continue the splinting for another month after removal of the wires.¹¹⁶ Early mobilization is encouraged with rigid fixation of autografted bone.⁹⁹ In cases of callotasis bone formation, the distractor is worn for a total average time (that is, distraction plus consolidation) of 10.4 weeks to upward of 4 months, depending on the author.^{8,92-97}

Free Neurovascularized Toe Transfer

Dressing, immobilization, and other details of postoperative treatment are found in Chapter 51.

TREATMENT OUTCOMES AND COMPLICATIONS

In addition to the most common surgical complications that can occur intraoperatively (such as bleeding and damage to underlying structures) and postoperatively (such as problems with the dressing and infection), there are some complications particular to each of the various procedures previously described.

Web-Deepening Procedures

In web-deepening procedures, “shallowing” caused by scar contracture can necessitate repeat surgery. Skin graft loss after syndactyly release, although uncommon, may require repeat grafting, and often the need to switch to split-thickness skin grafts to improve the chance of “take.”

Bone-Lengthening Techniques

Free Toe Phalanx Transfer

In free toe phalanx transfer, if the chosen phalanx is either too wide or too long for the skin sleeve for which it was intended, the incision can dehiscence or skin necrosis can occur.^{5,6,71,87} Phalangeal displacement or instability can also take place.⁸⁶ Because the flexors have a stronger pull than the extensors, a flexion contracture can arise, particularly when the base of the phalanx is transferred to reconstruct a new metacarpophalangeal joint (J. Upton III, personal communication, 2006). Occupational therapy and splinting may help to correct the problem, which can be prevented by incising the tendinous “cap” so that the flexor component is somewhat longer in relation to the extensor component, as previously described. Damage to the epiphysis with subsequent fusion of the growth plate has been reported.⁸⁶ Resorption, with subsequent shortening, is particularly likely when the distal end of the toe phalanx has been removed during transfer.⁸⁶ If the surgery is undertaken after the child reaches 2 to 4 years of age, there may be little or no growth of the transferred phalanx,^{71,86,87,89} which also sometimes occurs in children who are operated on before 18 months of age.⁸⁶

The donor toe shortens if bone grafting of the donor site is not done, and can shorten even more if the flexor and extensor tendons are not sutured together to partially fill the donor defect.^{6,87} Shortening also occurs if there is damage or transection of the flexor tendon at surgery.⁸⁶ The toe remains unstable if bone grafting is not undertaken^{6,71} and may become displaced dorsally because of scar contracture of the dorsal incision or cross over an adjacent digit.⁷¹

On-Top-Plasty and Ray Transposition

In on-top-plasty and ray transposition procedures, the complications that are most likely to occur include neurovascular difficulties, problems with stabilization and correct positioning, and limited tendon function (that is, contracture⁶ or adhesions).

Distraction

In gradual distraction, problems with the distractor itself may occur. These can be mechanical in nature, including insufficient length of the apparatus to achieve the desired distraction,⁹⁵ breakage, wear and tear, poor upkeep, or even loss of the key.⁹⁹ Complications may also occur as a result of incorrect installation of the apparatus. Examples include the following: bending of the K-wires^{92,99} or fixation pins because of their inadequate size; placement of the fixation bar too close to the skin, thus causing injury⁹⁹; incorrect incision and positioning of the pins or wires with resultant tearing of the soft tissues⁹⁹; loosening of fixation into the bone⁹⁴ or tearing through it³²; extrusion,⁹⁹ angulation,^{94,99} or rotational deformity; and pseudarthrosis.⁹⁹ Even the palmar skin under the splint or dressing can be vulnerable.⁹⁹

Prolonged paresthesia of the digit^{88,98} is occasionally attributed to the use of the finger trap in one-stage distraction lengthening.⁹⁸ It can also be a result of excessive distraction of the neurovascular pedicle^{5,6} and may require slowing of the distraction rate.⁶ Pain, soft tissue damage,⁹⁹ fibrosis,⁹⁹ and bone exposure are possible if distraction is too rapid.⁹⁹ Bony prominences may also appear at the fingertips in cases of terminal bone distraction. These may be painful,^{94,96} necessitating stopping the distraction,⁹⁶ or performing other procedures such as trimming the bone or providing flap coverage.⁹⁴ Slowing of the distraction rate may be necessary with healing difficulties of the wounds^{5,6} or the skin bridge between the K-wires.⁵ Vascular compromise of the skin,^{5,6,39,88} pain,^{5,6,88} and progressive contracture may also require slowing of the distraction rate^{6,88} or stopping it altogether for a day or two.³⁹ Distraction of a more proximal bone, such as a metacarpal bone, can result in the progressive development of a flexion deformity at more distal joints, unless these are pinned in extension.^{5,6,88} There may be some loss of motion after distraction.^{95,96} Tendon adhesions may also be at fault in cases of distraction with secondary bone grafting, and these may require tenolysis.⁹⁹

An incorrect skin incision and placement of pins can result in maceration around the pins.⁹⁹ Development of a pin tract infection^{94,96} cannot always be avoided,⁸⁸ and can be caused by inadequate cleaning⁶ or nonrigid fixation of the device, as can osteomyelitis.⁹⁹ In the study by Dhalla et al,⁹⁴ all of the cases of infection occurred in patients treated with a single half-pin on either side of the osteotomy and longitudinal K-wire fixation during distraction; there were no infections in the double half-pin group. This may be caused by exposure of the intramedullary K-wire to the environment, thereby increasing the risk of infection. In their discussion, the authors suggest prophylactic antibiotic use in patients with single half-pins and a longitudinal K-wire distraction technique. They propose continuing the use of perioperative cephalexin for 2 weeks postoperatively and restarting it for another 2 weeks in the presence of pin track drainage or cellulitis. In some cases of deep infection, intravenous antibiotics may be necessary and the distraction device may have to be removed.⁹⁴ In patients with this complication who are undergoing callotasis bone lengthening, splinting may be sufficient to achieve consolidation, although secondary bone grafting may be required.^{8,94} Cold intolerance in patients living in cold climates is not unusual in children and is almost universal in adults.⁹⁹

Difficulty in achieving the planned length may result from fusion of the osteotomy site during distraction⁹⁷ or the use of the immediate bone-grafting technique. Final outcome can also be affected by bony angulation,^{88,94,96,99} pseudarthrosis,⁹⁹ or malposition.^{6,88,99} These sometimes occur when the rigidity of fixation is insufficient or when range-of-motion exercises are started too soon.⁹⁹ In cases of distraction with secondary bone grafting, malposition during distraction can sometimes be corrected at the time of the bone graft.⁶ Callotasis distraction lengthening may also occasionally require secondary bone grafting if callus formation is inadequate to achieve consolidation.⁹⁵ Fracture, during consolidation or after removal of the fixator, in callotasis lengthening⁹⁴ may complicate the final result. In cases of secondary bone allografting, sequestrum formation or fracture of the immobilization plate have been reported.¹¹⁶ Direct or vascular trauma to the epiphysis can affect the growth⁹⁹ of adjacent bones. In some cases, the lengthened and nonlengthened neighboring bones may not continue to grow in relative proportion to the rest of the hand, resulting in the worsening of initially acquired function such as pinch.⁹⁶ Finally, hypertrophic scarring⁹⁵ can downgrade even an excellent result.

Free Neurovascularized Toe Transfer

For toe-to-hand transfer, complications are detailed in Chapter 51. In addition to these, there can be problems associated with inadequate length, incorrect positioning, and limited motion of

the transfer. Limited motion of the transfer can be associated with poor quality of the proximal motors, which is most often seen in the more proximal forms of symbrachydactyly.⁷¹ Inadequate length and incorrect positioning are most often caused by poor initial planning. When multiple toes are transferred from the same foot, donor site defects can be disfiguring.¹⁰⁰ Adult patients with combined second and third toe transfers for congenital or traumatic injuries have more foot problems than those undergoing a single toe transfer.¹²⁰

Joint Stabilization Operations

As with any fusion technique, malunion and nonunion are potential pitfalls, especially when bone stock is deficient. It is important to treat soft tissues gently to avoid necrosis or healing difficulties of the soft tissue sleeves covering severely hypoplastic digits, or nail damage. Reconstructing ligaments to stabilize a joint while maintaining its mobility, when the joint surface area is inadequate, is aiming too high and will often result in failure requiring secondary fusion.

Other Corrective Procedures

Complications after other corrective procedures are similar to those found in normal hands undergoing the same procedure. It is nevertheless important to take into account that the structures are often smaller and/or hypoplastic, requiring adjustments in technique and reasonable expectations when planning surgery.

FUTURE DIAGNOSTIC AND TREATMENT MODALITIES

Improvement in the classification of this group of malformations would go a long way to gaining a better understanding of the genetics, incidence, associated malformations, and syndromes that can accompany several of the categories of undergrowth. It would facilitate the comparison of outcomes using various techniques of treatment with the aim of developing treatment algorithms according to the subclass and severity of a specific malformation. This would be particularly useful in clarifying the place of each of the many procedures described for the treatment of the various malformations presently classified as undergrowth. Furthermore, collaborative multicenter efforts would contribute to improving the care of all patients with hand malformations, particularly those with the rarer forms, as would well-maintained, complete diagnoses and complication registries.

Work in the genetics of hand malformations may eventually aid in the understanding and perhaps even in the treatment of certain hand malformations. Perhaps tissue engineering will provide eventual availability of “spare parts” for surgery. Although several hand transplants have been undertaken in adults, none has yet been performed in a child. Concerns about long-term immunosuppression and, in congenital hand cases, deficient recipient structures slow development in this area.

In the meantime, work is progressing in myoelectric prostheses, including improved motor control with the use of nerve transfers¹²⁵⁻¹²⁷ and research in the development of sensory feedback.¹²⁸ Most of the work is done in adult traumatic amputees, although some teams have been working with preschool and early school-aged children.¹²⁹ It is of note that, even if fitted at a young age, over half of children with absence of the segment at or distal to the wrist, will not use their prosthesis.¹²⁹ More recently, three-dimensional printers and devoted volunteers have given access to light, low-cost, colorful plastic mechanical hand prostheses that can be assembled by the patient and family and easily replaced as the child grows.¹³⁰

KEY POINTS

When to Operate

- Surgery should be reserved for patients with functional problems or when there is a clear functional benefit to intervening. It is paramount that the expectations of the surgeon, patient, and family be reasonable and realistic before embarking on a long and complicated reconstructive plan with all its potential risks and problems.
- Because patterns of hand function are generally established between the ages of 6 months and 2 years,¹⁰⁶ with thumb opposition beginning at approximately 7 months of age,¹⁰⁷ most operations modify the way the hand and the digits are used and thus are best performed before 2 years of age. Therefore, in chronologic order:
 - When a free phalanx transfer is appropriate, surgery should be undertaken under 1 or 2 years of age, and probably not after 4 years of age if one desires growth of the phalanx. For best results, the periosteum and ligaments should be kept intact.
 - Although amputation of tiny flail nubbins can be undertaken at any age, it may be wise to wait until it is clear that the nubbins are not useful for function and that a free toe phalanx transfer is either inappropriate or unwanted before proceeding. Similarly, ray amputation of a useless digit should not be undertaken before considering all potential uses for it. This should include development of a clear long-term plan that considers the possibility of transferring the digit or any of its components at a later stage during the process.
 - On-top-plasty and ray transposition are not commonly performed procedures; therefore there is not much in the literature about the ideal age at which these surgeries should be performed. Because these operations are mostly used to reconstruct the rays around the first web space, surgery should probably be performed early, but perhaps after the age of increased vasospasm. Between 1 and 2 years of age seems reasonable.
 - When possible, syndactyly release or multiple Z-plasties should be withheld until the patient can cooperate with postoperative care (after 3 years of age), unless there is a functional problem necessitating early intervention. In such a case, some operate on children at 6 months of age or younger, although waiting until they are 9 to 12 months of age facilitates surgery and decreases neurovascular risk as well as flap necrosis.
 - Ligament reconstruction, metacarpal rotation osteotomy, tendon transfers, and various other corrective interventions should be undertaken when the structures are large enough to allow stable, solid fixation. This usually means sometime during the preschool or early school years, be-

tween 4 and 6 years of age, or even later if the structures are particularly underdeveloped. Joint fusion should usually be delayed until the growth plates are closed to prevent secondary growth retardation resulting from trauma to the physes in bones that are already short. Some surgeons, nevertheless, may feel comfortable undertaking chondrodesis in younger children.

- In patients for whom distraction lengthening, with either immediate bone grafting, secondary bone grafting, or callotasis bone formation, is an appropriate modality, the age at which treatment is undertaken varies greatly in the literature. For this reason, surgery before school age should be considered in those patients in whom the potential functional benefits outweigh the risks. Otherwise, it is suggested to wait until there is good understanding and collaboration on the part of the patient, until larger bones permit more rigid fixation, and until there is less risk that disproportionate growth of the various elements of the hand will undo the correction—perhaps even as late as adolescence.

Interdisciplinary Approach

- Because of the complexity in treating some cases of undergrowth, it is suggested to have a well-integrated interdisciplinary approach for some patients:
 - Pediatrics and/or medical genetics can screen for syndromic cases and refer the patient to other relevant specialists or multidisciplinary clinics.
 - Occupational therapy and/or physiotherapy can evaluate function, help plan treatment, undertake postoperative therapy, and follow the patient for deterioration with growth.
 - Psychologists and/or social workers can assess the patient's and family's ability to cope with the malformation and multiple proposed interventions, as well as support the patient during various stages of treatment and life's milestones.

The Treatment Plan

- Very mild cases of undergrowth require no treatment at all.
- More significant digital shortening may benefit from syndactyly releases to improve handbreadth, but at the expense of scars, which may or may not be considered a fair exchange in the eyes of some families.
- Various reconstructive procedures such as first metacarpal rotational osteotomies, tendon transfers, ligament reconstructions, joint fusions, on-top-plasties, ray transpositions, use of nonfunctioning bone segments as grafts, and so forth, must be considered and planned at the onset, even if the actual surgery is not going to be undertaken until much later.

Continued

KEY POINTS (continued)

The Treatment Plan—cont'd

- Because phalangeal lengthening does not permit the creation of new joints, which results when they are elongated excessively in stiff, thin digits, distraction is more often used for the metacarpals. When used for phalanges, the technique is probably most appropriate when there is not only significant shortening but also an associated deformity, such as angulation, that requires correction. It may be useful to consider distraction of an otherwise useless segment with the aim of transposing it as an on-top-plasty, usually on either side of the first web. Distraction is also useful for the reconstruction of pinch, including its use for some ray transfers.
- The choice of a distraction technique depends not only on the preference of the surgeon, the patient, and the family, but also on the amount of lengthening required. Distraction lengthening with immediate bone grafting permits approximately 5 to 15 mm of lengthening. Distraction lengthening with callotasis bone formation achieves approximately 10 to 30 mm of additional length. Finally, distraction lengthening with secondary bone grafting permits approximately 25 to 70 mm of lengthening.
- A free toe phalanx transfer can be considered in young patients (less than 1 or 2 years of age, and rarely after 4 years of age) to stabilize flail skin sleeves. The result is superior when the metacarpophalangeal joint is present and actively mobile.
- Amputation should be reserved for tiny, flail nubbins that are not useful functionally and cannot benefit from a free toe phalanx transfer. Ray amputation is indicated for a flail, single hypoplastic digit in a normal or near-normal hand.
- Multiple Z-plasties permit deepening of the web that is present between a remaining thumb and the little-finger ray in patients with oligodactylic/apthalangic symbrachydactyly. This procedure widens the breadth of the grip, allowing the patient to grasp larger objects without losing fine pinch. The intervening hypoplastic metacarpals should not be further shortened before making sure that they are not useful in stabilizing grip.
- A free neurovascularized toe transfer is recommended for more severe cases requiring reconstruction of some form of pinch. The aim is to achieve a two- or three-digit pinch, including any available digits in the hand that can be reconstructed or stabilized. It is important to note that the more proximal the deficit, the more severe the malformation and the less likely that adequate proximal motor function is present. This can affect the final range of motion and end result. Anticipated range of motion must be taken into consideration when planning the surgery, including positioning and adjustment of the transfer.

The author evaluated 57 patients who had 97 free toe phalanx transfers to the hand, averaging 40 months of age at surgery, with nearly 50% under 18 months of age. The operative procedure is described, and the importance of including the collateral ligaments and plantar plate in the transfer is emphasized. Complications included seven cases of wound dehiscence or marginal skin necrosis, two cases of phalanx dislocation, and no foot complaints or functional disability at the donor site, despite toe shortening in 79.7% of donor toes, which was less marked in cases where the toe tendons were sutured together to serve as a spacer. At follow-up, which averaged 40 months, the patients were divided into three groups according to age at surgery: 7 to 18 months, 19 months to 4 years, and 4 to 17 years. In the youngest age group, the growth plates remained open in the highest percentage of grafts (65.7%) compared with both groups of older patients (26.7% in the intermediate age group and 15.8% in the eldest patients), whereas the intermediate age group had the greatest average growth (3.5 mm) compared with either the younger (3 mm) or older patients (1.5 mm). Despite modest measurable gains, the functional hand improvement was considered remarkable in all cases.

Two techniques used for callotasis distraction lengthening of terminal bones in children were described. Seven digits had large enough bones (average length 30 mm) to permit more traditional dual half-pin fixation on either side of the osteotomy. Twenty digits had bones that were too small (average length 18.3 mm) to accommodate the four half-pins necessary for the traditional method and thus had lengthening over a longitudinal wire using one half-pin on either side of the osteotomy site. In the first group, average lengthening was 14 mm and in the second group 11.5 mm. There were more complications in the second group, including the only cases of infection (7), pin loosening (3), and angulation (2). Despite a complication rate of 43% in the first group and 75% in the second group, none of the complications were considered to have affected the final outcome.

The authors described 40 cases of free neurovascularized toe transfers to the hand in children, with 14 having two second toes transferred at the same operation. Of these cases, 85% were performed for congenital malformations: 18 cases of symbrachydactyly or Poland's syndrome and eight transverse deficits; some of the transverse defects may qualify as cases of "undergrowth." The surgical technique is explained, as are the complications, subsequent growth, and further operations undertaken. In the discussion, the authors explain their decision-making process in the reconstruction of congenital hand malformations, including the use of, at most, two second-toe transfers, one from each foot, and other pertinent details that they feel to be important for good results.

This companion study to their previous paper describes 40 cases of free neurovascularized toe transfers to the hand (14 had two second toes transferred at the same operation) in children. Eighty-five percent were performed for congenital malformations (18 cases of symbrachydactyly or Poland's syndrome and eight transverse deficits [some of transverse deficits may qualify as cases of "undergrowth"]). The motor and sensory function of the transfer, donor site problems, and the psychosocial outcome were evaluated in 37 patients, on the average 45 months postoperatively. The total active range of motion of the transfers was 60%, with motion in all evaluated cases except for three. All except for three transfers (one of which had no motion) were useful and incorporated naturally into grip function. Sensation recovered with an average two-point discrimination of 5 mm, although 28% of patients tested had only protective sensibility at Semmes-Weinstein monofilament evaluation. There were two cases of pain in the transfer, but half of the patients had sensitivity to cold. There were some minor complaints at the donor site, including five patients who had hypersensitivity near the scar, pain on walking long distances, and slight problems in fitting their shoes. Eighty-four percent of parents and 88% of the patients thought that there was an improvement in appearance of the hand, and 92% of the parents and 100% of the patients thought there was an improvement in hand function.

Amniotic Band Syndrome

Madeleine J. Gust • Gregory A. Dumanian

central feature of *amniotic band syndrome* (also known as *amniotic band sequence*, *constriction ring syndrome*, *congenital constricting bands*, and *congenital ring syndrome*) is the presence of asymmetrical, nonanatomically distributed, soft tissue abnormalities of the extremities. Extremity malformations can be classified into five major groups, first proposed by Patterson¹ (Fig. 49-1). Anomalies that can occur in association with amniotic band syndrome include clubfeet, facial clefts, cleft lip and palate,² body wall defects,³ and cutis aplasia. The most severe cases may lead to anencephaly or fetal demise.⁴ Most cases are sporadic. The estimated incidence is approximately 1 in 10,000 live births, with an equal sex distribution.^{1,5} No genetic associations have been found,^{1,6} and more than half of documented cases in one report had abnormalities during gestation, including prematurity, maternal illness, low birth weight, and maternal drug exposure.⁷

GENETICS AND CAUSE

Numerous observers since the time of Hippocrates have described newborn infants with apparent amniotic band syndrome. Van Helmont of the early seventeenth century was one of the first to describe an intrauterine amputation.⁸ Montgomery,⁹ in 1832, described free strands of tissue located at the site of a constriction band. Intrinsic and extrinsic mechanisms have been proposed.

In 1930 Streeter¹⁰ stated that the cause of the constriction ring syndrome was intrinsic to the fetus. Inadequate fetal “germ plasma” leads to a local degeneration of soft tissue in a manner analogous to a cleft lip and palate. The intrinsic theory survives, because of a higher-than-expected association of this syndrome with internal malformations such as absent or dysplastic kidneys, ectopically placed gallbladders, imperforate anus, and loss of the abdominal wall. The intrinsic theory is supported by cases of amniotic band syndrome in twin gestations. In most twin gestation cases, both fetuses are affected, suggesting a phenomenon that is systemic (genes, maternal factors, or teratogens) rather than local. Streeter hypothesized that the fibers seen at the bases

Fig. 49-1 The major consequences of amniotic bands, modified from the Patterson classification.¹ (I, Shallow constriction; II, deep constriction with distal involvement $\pm$ lymphedema; III, constriction with distal fusion (acrosyndactyly); IV, in utero amputation; V, mixed [can include fusion of the amputated part to a different finger].)

of bands were attempts at fetal wound healing. Finally, breaches of the amnion (a cornerstone of the extrinsic theory) occur with each successful amniocentesis performed, yet the incidence of amniotic band syndrome does not increase after this procedure.¹¹

The favored theory postulates an extrinsic pressure applied to the tissues of the growing fetus. The extrinsic theory, particularly its description of pressure and necrosis of tissue, makes intuitive sense to those in surgical fields. Torpin¹² hypothesized that amniotic band syndrome is caused by an in utero tear in the placental amnion. The fetal skin is in continuity with the amnion at the umbilicus, and deep to the amnion is the chorion. When the amnion ruptures spontaneously early in the middle trimester, it can separate from the chorion. This produces tiny strands of free-floating tissue. The fetal hands and feet, because of their waving motion, “catch” these 1 to 2 cm long strands. If the strands were to embed into the fetal skin, further growth of the rapidly enlarging fetal extremity would be limited, resulting in a constriction ring of variable severity. Rarely, these strands can be recovered from the base of a newly born infant with amniotic band syndrome. In one case, Kiehn et al¹³ released a fibrous band of inelastic material from the leg of a twin born at 27 weeks with an underlying constriction ring. Mechanisms by which these strands can cause various types of anatomic changes in fetal limbs are easily postulated.

Rupture of the amnion causes a temporary oligohydramnios because of exposure of the amniotic fluid to the relatively permeable chorion. Oligohydramnios persists until the chorion thickens (Fig. 49-2). Oligohydramnios and increased intrauterine pressure on the fetus can explain the coincidence of clubfoot and cleft palate (akin to Pierre Robin sequence) with the amniotic band syndrome.¹⁴ A recent report of iatrogenic pressure on a growing fetal limb as a cause of a constriction band supports the extrinsic hypothesis.¹⁵

In utero amputations provide a clue about the timing of the amnion rupture and the onset of pressure on the developing limb. This was documented in several cases in which the amputated

Fig. 49-2 Chorioamniotic separation.

piece was located after the birth of the child. In most of these cases, the amputated limb had a gestational size of older than 14 weeks and younger than 20 weeks.

A fetus can swallow large amniotic cords. This draws the vertex of the fetus toward one site on the placenta.¹⁶ The direct contact, restricted motion, and constant pressure of the fetal head on the placenta may be a cause of the cutis aplasia sometimes seen with amniotic band syndrome (akin to a fetal pressure sore). Nonanatomic perioral clefts are associated with the syndrome and hypothesized to be caused by the indentation of a swallowed cord on perioral tissues.¹⁷

DIAGNOSIS

Prenatal

Prenatal diagnoses with fetal ultrasound and fetal MRI facilitates prebirth counseling and preoperative planning. For the past 20 years, ultrasound has been useful for identifying swollen limbs and areas of constriction. Three-dimensional ultrasound helps parents to appreciate the deformity and surgeons to start planning and having discussions with the parents prenatally.¹⁸ Some constricted areas seem to resolve spontaneously; therefore serial ultrasound examinations of the fetus are important.¹⁹ One report documented decreases in blood flow distal to the constriction band, which identifies limbs at risk for in utero amputation.²⁰ For limbs at risk, fetoscopic release of bands has proved feasible in selected centers, again necessitating a balance between the health of the fetus and the mother and the survival of the limb.²¹ In a review of seven cases of fetoscopic release of amniotic bands, Hüsler et al²² found premature rupture of membranes in 71% of patients, delivery at a median of 34.8 weeks, and one case of intrauterine fetal demise. One case without limb perfusion at the time of fetoscopic release eventually required amputation after birth, and another case with failed fetoscopic release nonetheless had a good outcome with surgery after birth. The authors concluded that the cases likely to improve had abnormal but present blood flow distal to the constriction band.

Postnatal

The hallmark of amniotic band syndrome is an inelastic transverse extremity band of variable width and depth. Tissues proximal to the ring typically appear normal. The patterns of extremity involvement are varied—a single extremity can be affected at several levels, and each patient often has multiple extremities affected. The bands can be shallow or deep and result in distal fusion or in utero amputation. The middle and ring fingers are the most commonly affected.²³ The thumb is somewhat spared because of its short length and relatively protected abducted volar position in utero. Affected digits have a high percentage of fingernail hypoplasia or absence (Fig. 49-3).

Differential Diagnosis

The diagnosis of amniotic band syndrome is relatively straightforward for cases of deep bands with concomitant distal deformity (such as lymphedema). The diagnosis is less straightforward for infants born with syndactyly, acrosyndactyly, or apparent in utero amputations, because these conditions can occur in isolation. To make the diagnosis for children with amputations or acrosyndactyly, another finding such as involvement of an additional extremity, cutis aplasia, clubfoot, facial clefts, or abdominal wall defects is needed. Other distinguishing features on a physical examination of the infant indicate this syndrome. For amputations, bare bone of apparent normal size may be found protruding past the level of the soft tissue amputation, as if a guillotine amputation had been performed and the soft tissues had retracted. This is in contradistinction to cases of transverse arrest, in which atretic soft tissues cover a hypoplastic bone. Amniotic band syndrome patients with acrosyndactyly have the unusual physical finding of epithelialized sinuses at the bases of the fused digits. Finally, adjacent to an amputated digit, the adjacent piece of soft tissue often appears enlarged, as if a portion of the amputated digit has survived in part as a soft tissue graft. These subtle findings from a physical examination suggest a slow ischemic insult to the tissue distal to the constriction band.

Fig. 49-3 The left hand of a 10-month-old infant with amniotic band syndrome. The index finger suffered an amputation in utero, and a portion of the digit survived as a graft onto the dorsum of the middle finger. **A**, Anterior view. **B**, Posterior view.

CLASSIFICATION, TIMING, AND SURGICAL MANAGEMENT

The natural history of minor constrictions is variable. Patterson¹ thought the bands were most noticeable at birth, because the indentations are elevated in high relief by an infant's baby fat. In contrast, Flatt²³ wrote that in more than 50% of the infants, the constriction worsens over time because of cicatricial healing of granulation tissue at the base of the bands. For this reason, children with shallow constriction rings should be followed closely after birth. In a case report, Ho et al²⁴ treated a premature, critically ill infant born with a well-vascularized soft limb that progressed to dusky and tense on day 4 of life. The child required an emergent simple band release at the bedside, and the edema resolved. Samra et al²⁵ and Weinzwieg²⁶ also presented cases of rapid limb swelling and vascular compromise after birth that improved with immediate surgical intervention.

We propose a modification of Patterson's classification system, with some insight from Weinzwieg²⁶ and Hall et al,²⁷ who noted, respectively, the importance of distal lymphedema and evolving vascular compromise, and we add a focus on neuronal involvement.¹ Our system attempts to base treatment on anticipated limb function and to aid in determining the best timing and type of surgical management (Fig. 49-4). This classification ranks the deformities from the most to the least urgent. Deep constriction bands with vascular or nerve involvement are urgently

Fig. 49-4 Amniotic band syndrome classification and treatment algorithm.

addressed, whereas less urgent deformities, including deep constriction bands with venous or lymphatic congestion and acrosyndactyly, can be treated within days to months after birth. In utero amputations do not require urgent treatment and, if indicated, can be reconstructed when patients are 6 months to 1 year of age. Finally, shallow constrictions are treated as an elective procedure based on the degree of cosmetic deformity.

Shallow Constriction Bands

The indication for treating stable, shallow constriction rings is cosmesis. The severity of a cosmetic deformity should be balanced against the risk of anesthesia when deciding the optimal timing for revision. As a child ages, the neurovascular structures become larger and easier to dissect. Though it is a matter of opinion and clinical practice, shallow bands are generally not treated in our center before patients are 3 to 4 years of age unless they are in the operating room for another reason.

Similar to the surgical procedure described by Upton and Tan,²⁸ the treatment of shallow constriction bands includes loop magnification and excision rather than incision of the band (Fig. 49-5). After skin flap elevation, subcutaneous fat flaps are developed, and the dorsal aspect of a prominent fat flap can be debulked. The fat flap is mobilized across the band for improved contour, and a straight dorsal closure is performed. Finally, Z-plasties are performed on the lateral aspect of the digit or extremity (Fig. 49-6). Shallow bands may be completely revised in one procedure, even if the band is circumferential, and results tend to be quite good.^{28,29}

Fig. 49-5 Schema for repair of an amniotic band of a digit.

Fig. 49-6 The thumb of the hand shown in Fig. 49-3, treated for an amniotic band. **A**, Excision of ring and midlateral Z-plasties are marked. **B**, Skin flaps are retracted to contour the dorsum of the fat of the digit. **C**, Fat flaps are mobilized across the band. **D**, The thumb is shown after skin closure.

Although early methods of amniotic band reconstructions of the limbs have included circumferential Z-plasties, more recent articles have proposed modifications including turnover dermatofascial flaps with rectanguloplasty instead of Z-plasty to orient the scars along relaxed skin tension lines.³⁰ Another article proposed straight-line closure to further decrease scar burden.³¹ The authors thought it reasonable to perform a straight-line closure with two posterolateral Z-plasties in the limb (as shown in Figs. 49-5 and 49-6) to combine the advantage of a straight-line scar with the minimization of scar contracture by the Z-plasties in areas that are less visible. The unifying theme of all techniques is complete excision of all segments of the amniotic band.

Deep Constriction Bands

Most surgeons generally agree that staged treatment of deep constriction bands is safer than a one-stage circumferential revision. Staged treatment is thought to lessen the chance of distal circulatory compromise caused by perioperative swelling, tissue trauma, and interruption of subdermal plexus circulation. The second stage is performed 2 to 3 months after the first procedure. Surgical principles are similar to those followed for treating more shallow bands. Great care is taken to preserve all veins and lymphatics that run longitudinally across the band. An operating microscope is useful for this.

A one-stage repair of deep circumferential bands with distal involvement is performed in some centers. They correctly think that it prevents a second trip to the operating room^{27,32} and may reduce possible digital compromise from postoperative swelling and potentially tight dressings. They argue that, because of the deep bands, venous and lymphatic flow are already channeled along the tendons of the finger and along the fascia of the extremity and therefore would

not be divided by a circumferential skin incision. The location of the arteries is predictable, and these can be protected during the dissection.

Limb Ischemia

The most urgent and most difficult deformities are related to deep constriction bands. For such bands with documented limb ischemia, we recommend surgery within hours to days of birth. The discussion with the family needs to include the possible need for vascular and nerve grafts and the possibility of long-term growth restrictions and permanent nerve deficits if the release is not performed. We recommend reconstructing underlying major nerves and vessels with grafts at the initial surgery. In one study of 8 patients with a total of 20 affected limbs, 100% of the limbs with deep bands or with amputations were found to have anomalies or absence of major arteries proximal to the band on MRA or CTA, whereas superficial bands had only an 11% incidence of an underlying vascular anomaly.³³ Weinzwieg²⁶ concluded that this may be secondary to distal maldevelopment and thus attrition of the blood supply or lack of formation of the normal vascular pattern. Weinzwieg²⁶ showed good short-term outcomes with immediate decompression to evacuate lymphedema fluid, staged band excision, Z-plasty, and local wound care for distal tissue necrosis. Samra et al²⁵ presented a 6-year follow-up of a significantly compromised limb that was salvaged by immediate excision of two thirds of the band, followed by release of the remaining third a week later and sural nerve grafting to the sciatic nerve at 6 months for lack of motor and sensory function. The 6-year outcome included a 5.5 cm leg length discrepancy and decreased sensation on the dorsum of the foot; however, all other sensation and motor function had returned, and the patient was able to run, ride a bike, and balance on each foot.

Nerve Involvement

Nerve involvement caused by compression and/or ischemia with associated sensory or motor dysfunction at birth are additional severe manifestations of amniotic band syndrome. Surgery with nerve grafts is recommended within hours to days of birth. In an interesting subset of patients, nerve morphology distal to the constriction appears normal, suggesting that the ring occurred after the formation of the nerve trunks. In several instances, the intraoperative appearance of the nerve did not correspond well to the preoperative assessment of nerve function clinically or by nerve studies.^{34,35} Despite early (3 to 6 months) exploration and intrafascicular release, long-term return of function has not been exceptional. This has led some surgeons to advocate even earlier surgical releases of the involved site and being ready to excise and graft the nerve across the constriction site.³⁶

Lymphatic or Venous Congestion

Less severe constriction bands only affect the low-pressure venous and lymphatic systems. The distal edema is thought to be of lymphatic origin. Patients with deep rings often have temperature differences of several degrees centigrade between affected and unaffected digits. Typically, distal affected skin becomes violaceous after cold exposure. Early release of the band reduces the pressure gradient that must be overcome for lymphatic return. The more congested the distal extremity, the earlier the revision of the band must be performed. For significant congestion, surgery is recommended within days to weeks to prevent long-term sequelae.

In a physical examination, generalized swelling distal to a constriction ring should be distinguished from a localized, nonswollen mass distal to a band. For patients with a localized, non-

Fig. 49-7 The right hand of the same 10-month-old infant (see Figs. 49-3 and 49-6) with acrosyndactyly. A snap passes atraumatically through the base of the web space.

swollen mass distal to a band, if an adjacent digit had an in utero amputation, the mass may be the remnants of the amputated digit that survived by grafting. Therefore this digit with a localized mass can be treated more like a digit with a shallow constriction band rather than urgently, like an extremity with a deep constriction ring.

Acrosyndactyly

Acrosyndactyly is from the Greek *akros*, meaning “topmost.” It is constriction with distal fusion of soft rather than bony tissue, with more distal versus proximal involvement. Patterson¹ has further subdivided acrosyndactyly into the following:

- I Fingertip fusion with webs intact
- II Fingertip fusion with partial webs
- III Fingertip fusion with sinus tracts, but no webs

Most cases have at least some degree of web space shortening. When multiple digits are involved, the digital tips are said to resemble a small bunch of grapes, and assigning a fingertip to its appropriate digit is quite difficult (Fig. 49-7). Surgical release should be performed by 3 to 6 months to maximize the chance for proper longitudinal bone growth and to allow the child to use the fingers independently.^{37,38}

Surgery for these patients follows the principles used to treat an Apert hand. Full-thickness skin grafts are used liberally; web spaces are reconstructed with broad flaps (the skin of the sinuses is not overly broad or helpful); digits are resected when appropriate; and surgery should be restricted to one side of a digit at a time to prevent vascular compromise.

When all five digits are involved, we typically follow a sequence to release the first and third web spaces at the initial procedure, followed by a release of the second and fourth spaces. This allows a two-stage release of all digits without the need to perform a procedure on both sides of the same digit. Further deepening of the web spaces by release of the deep transverse metacarpal ligament with or without intrafascicular nerve dissection may also be necessary to lengthen the short digits in cases of severe acrosyndactyly.

Fig. 49-8 This untreated adult with amniotic band syndrome has no complaints regarding hand function.

In Utero Amputations

Little is written concerning the management of children with in utero amputations, possibly because the indications for active intervention are few. In comparison to cases of transverse arrest, patients with amputations from amniotic band syndrome do not have associated soft tissue digit nubbins; therefore they do not need revisions for cosmesis or function. Adults with loss of multiple digits by birth often have near-normal hand function (Fig. 49-8). Patients with unilateral involvement typically report that they use the affected limb as a helper, and involved reconstructions or prostheses are typically not necessary or indicated.

Infants with bilateral digital amputations may be helped by skeletal distraction for digital lengthening to improve grasp.³⁸ Alternatively, a resected second metacarpal can be used as a spare part to augment a congenitally amputated thumb.³⁹ This procedure simultaneously increases thumb length while it deepens the first web space. Finally, microvascular toe transfers are possible, because the toe tendons can be anastomosed to normal proximal tendons in the palm and on the dorsum of the hand. Surgeons can consider an “on-top” plasty, toe-to-thumb transfer, or web-space deepening as appropriate in patients 6 months to 1 year of age.

OUTCOMES

Long-term outcomes of surgery for amniotic band syndrome are mixed. The outcomes for shallow bands are uniformly good. However, growth disturbance seems to be increased with greater depth of the band and associated vascular compromise. One of my (G.A.D.) patients underwent a release of an upper arm constriction band, neurolysis of the median and ulnar nerves, and a brachial artery exploration at 7 months of age and continues to have arm length discrepancy and impaired function at her 6-year follow-up (Fig. 49-9).

Fig. 49-9 A, This 7-month-old female had a right upper arm constriction band, decreased arm growth, and a cool arm. B-D, Medial, lateral, and dorsal views show the patient at 8 months of age, after exploration of her right brachial plexus, multiple Z-plasty closure of the constriction band, neurolysis of the median and ulnar nerves, and exploration of the brachial artery. E and F, Two years postoperatively, the patient uses her left arm primarily and has decreased growth of her right upper extremity and no independent finger extension and flexion. She can make a composite grasp in extension and has good biceps and triceps function.

CONCLUSION

Advances in our understanding of amniotic band syndrome will continue to evolve. We will be at the forefront of these advances. Surgery has a wide range of applications from pure cosmesis to functional improvement and limb preservation.

KEY POINTS

- All patients with constriction bands should be examined early by a surgeon and followed closely for congestion and nerve or vascular changes during the first few weeks to months of life.
- Bands with nerve or vascular compromise should be treated aggressively and may need nerve or vessel grafts for reconstruction in the neonatal period.
- Deep bands should be released in a timely manner to prevent permanent swelling and dysfunction of the distal segment.
- Complete one-stage circumferential treatment should be avoided because of the risk of venous and lymphatic congestion.
- Patients with acrosyndactyly are analogous to patients with Apert syndrome, requiring large skin grafts for release of digits.
- Patients with full amputations often have excellent function and usually do not require surgical treatment.
- Shallow bands are cosmetic issues. The risks of treatment should be balanced against the potential benefits.
- Three-dimensional ultrasound has increased the accuracy of prenatal diagnosis and allows early family discussion and surgical planning; however, in utero fetoscopic band lysis, although successful in a few cases, carries significant risks of morbidity and mortality for a disease that is not life-threatening.

Generalized Systemic Conditions That Affect the Hand

Reuben A. Bueno, Jr. • Ronald M. Zuker • Benjamin Alman

Generalized systemic conditions can affect both the appearance and function of upper extremities. Regardless of whether the pediatric patient with a hand deformity or hand problem is seen with or without a known diagnosis, the consultant hand surgeon should be aware of the generalized systemic conditions that may affect the hand and upper extremity. In some presentations, the surgeon may be the first specialist to evaluate the patient and make a diagnosis. Although the presentations may vary, depending on the underlying disease, the common goal is optimizing the function of the hand and upper extremity. Surgery is only one aspect of a multidisciplinary approach for a patient with a systemic disease. As such, careful planning with realistic expectations is necessary when considering surgery to improve function and appearance. Treatment can be challenging—functional improvement may be temporary, because the propensity for recurrence is high in patients with systemic conditions.

MULTIDISCIPLINARY APPROACH FOR A PATIENT WITH A CHRONIC SYSTEMIC CONDITION

The chronic nature of many systemic diseases requires recognition by the hand surgeon that surgery is only one component in the total care of the patient. In addition to the general care provided by the pediatrician or family doctor, other specialists may need to be involved; for example, a neurologist for neuromuscular conditions, a rheumatologist for juvenile rheumatoid arthritis, a dermatologist for epidermolysis bullosa, or a geneticist for various contracture conditions.

Equally important to the management plan are therapists and nurses, who may be in contact with these patients on a more regular basis than physicians. If surgery is to be considered, input from all members of the multidisciplinary team should be sought to make the best recommendation for the patient.

GENERALIZED SYSTEMIC CONDITIONS THAT AFFECT THE HAND AND UPPER EXTREMITY

Many systemic conditions may affect the hand, and in some patients, the entire extremity. An adequate functional assessment of the hand must take into account the position and function of all the joints of the upper extremity, including the shoulder, elbow, and wrist. This chapter will address those conditions most likely to be seen by the hand surgeon, with consideration given to how these conditions affect the other joints of the upper extremity. These conditions include the following:

- Skin disorders: Epidermolysis bullosa (EB)
- Contracture disorders: Arthrogryposis
- Neuromuscular disorders: Cerebral palsy (CP)
- Inflammatory disorders: Juvenile rheumatoid arthritis (JRA)
- Hematologic disorders: Fanconi anemia (FA)

Skin Disorders: Epidermolysis Bullosa

Epidermolysis bullosa is a generalized systemic condition characterized by blistering, ulcerations, and scarring of the skin after minor trauma. The four major groups of EB are (1) EB simplex, (2) junctional EB, (3) dominant dystrophic EB, and (4) recessive dystrophic EB (RDEB). More than 20 subtypes of EB have been described.¹ Patients with EB have fragile skin; hands are especially susceptible to blistering and scarring because of the repetitive trauma of daily activities (Fig. 50-1). Patients with RDEB have the most deformed hands; patients with the Hallopeau-Siemens subtype are the most severely affected.²

Repeated trauma to the skin of the hand and subsequent scarring can lead to progressive deformity, ranging from flexion contractures at the interphalangeal (IP) joints (Fig. 50-2) to the characteristic *pseudosyndactyly*, which is caused by fusion of the web spaces, to “mitten” or “co-

Fig. 50-1 A, Dorsal and B, palmar views of the hands of a patient with EB. The thin, fragile skin is susceptible to recurrent blistering, ulcerations, and scarring from minor trauma.

coon” deformity (Fig. 50-3). This restrictive cocoon is composed of a hyperplastic epidermis, with a stratum corneum five times as thick as the remaining epidermis.³ Soft tissue scarring with the fingers and wrist in a flexed position can eventually cause joint contractures and bony erosion. Intrinsic hand muscles may also atrophy because of lack of use. There is variability in severity of skin and joint involvement in EB patients at presentation. Scarring at an earlier age has been associated with more severe deformities later in life.²⁻⁷ Hand deformities are seen in 95% to 98% of EB patients with the Hallopeau-Siemens subtype and in approximately 40% to 50% of patients with all other types of RDEB.²

Once the deformity affects hand function, nonsurgical options such as therapy and splinting are not effective to improve function or prevent worsening of the deformity. Because splints can result in repetitive trauma and scarring, they should be used judiciously. When considering surgery, all members of the multidisciplinary team must evaluate the patient’s overall health and ability to tolerate surgery. The quality of the skin, the patient’s nutritional status, and the involvement of other organ systems are assessed. The quality and amount of available skin are assessed, so that coverage with adjacent skin, a skin graft, or skin substitute can be planned. As the skin contracts and leads to worsening contractures, the joints of the digits and the wrist can become secondarily involved. Radiographs should be obtained to check for evidence of arthritic change and bony deformity. Surgical options will be affected by the presence of bony involvement. Evaluations by physical and occupational therapists should measure both the range of motion at affected joints and the patient’s ability to perform activities of daily living. Postoperative care includes immobilization, followed by splinting and therapy. Whether a patient can tolerate the

Fig. 50-2 Proximal interphalangeal (PIP) joint contractures in a patient with EB resulting from recurrent soft tissue scarring. Note the pseudosyndactyly from fusion of the web space between the ring and small fingers, as well as the loss of nail anatomy and shortening of the digits.

Fig. 50-3 Mitten deformity in a patient with EB.

postoperative regimen should be discussed before surgery, and input from all who provide care to the patient should be considered.

Because of the chronic nature of EB and the resulting progressive worsening of the hand, surgery should be viewed as a salvage procedure to preserve as much function as possible. Patients with the Hallopeau-Siemens subtype are the most likely to undergo surgery to improve hand function; these patients average three procedures per hand.² Unfortunately, there is no definable endpoint for hand surgery in an EB patient. As with other chronic conditions, the surgical plan must be individualized, taking into account the patient's overall health and level of function. During the preoperative period, nutritional status should be optimized with supplements and possibly a feeding tube. Hemoglobin levels should be measured; epoetin alfa (Epogen) has been used to prepare the patient for surgery. Hematologic consultation is recommended if Epogen is to be considered. Potential donor sites for skin grafts are evaluated, or arrangements are made for skin substitutes to be available for wound coverage. Because intubation may be complicated by involved mucosal epithelium of the airway, a preoperative consultation with the anesthesiologist is recommended. Esophageal stricture may also be present.

The surgical goal is to improve function by placing the involved digits in a more favorable position. To achieve this goal, digits that are coalesced together from repeated scarring need to be separated, scars must be released, and wounds need to be covered (Fig. 50-4, A through C). Adequate separation of the digits may first require web space release of the adductor pollicis and incisions at the distal interphalangeal (DIP) and PIP flexion creases to allow extension of the digits. Wound coverage is often the most challenging aspect of surgical treatment. Coverage op-

Fig. 50-4 A-C, Intraoperative release of mitten deformity. The digits were separated, K-wires were placed to maintain separation, and Apligraf was used for wound coverage. D and E, Postoperative results after the separation of mitten deformity, K-wire fixation, and application of Apligraf.

tions have evolved, from local flaps and skin grafts, to leaving the wounds open, to allografts.⁴⁻¹⁰ Allograft types include allogenic composite cultured, acellular allograft dermal matrix, and living cell skin substitute (Apligraf)⁸⁻¹⁰ (Fig. 50-4, *D* and *E*). No one method of wound coverage has been found to be consistently reliable in the EB patient.

As with all hand procedures, the two opposing aspects of postoperative care—immobilization and motion—must be balanced. The postoperative dressing should maintain the position after separation. Skin care must be a priority at every stage of the postoperative period, from the dressing, to splint formation, to motion exercises. Motion exercises usually start 4 to 6 weeks after surgery, and night splints are worn for up to 3 months. If surgery results in improvements, it is difficult to predict how long they will be maintained. The severity of the initial deformities, the patient's adherence to postoperative splinting and therapy, and the patient's overall health and nutritional status are important factors in the outcome of surgery. Surgical intervention has been shown to improve grasp and gross pinch, but maintenance of these gains has been difficult.⁶ Any gains made at the time of surgery should be considered temporary, and recurrence of the deformity should be expected in the future. Lifelong wound care with chronic skin blisters, joint contractures, and pseudosyndactyly should be expected. Research efforts focused on gene transfer, protein-based, and stem cell-based therapies hold some promise but may not be clinically applicable for many years.¹¹

Contracture Disorders: Arthrogryposis

Arthrogryposis is actually a physical finding, not a diagnosis. It represents a large group of disorders, all of which are characterized by the presence of joint contractures at birth. Arthrogryposis is sometimes used as a noun to describe specific diseases. As an adjective, *arthrogrypotic* refers to rigid joint contractures. More than 65 distinct syndromes are coded under the term *arthrogryposis* in the Online Mendelian Inheritance in Man (OMIM) database,¹² illustrating the large variety of causes associated with this term. Although each condition has a different clinical course, prognosis, genetic basis, cause, and pathophysiology, confounding surgical decision-making for an individual patient, a simple way to think about these disorders is to consider them as contracture syndromes. They can then be grouped into a few general categories, each of which can be represented by a prototypical disease that can be managed with shared principles.^{13,14}

The contracture syndrome groups are as follows:

- Those involving all four extremities: This group includes arthrogryposis multiplex congenita and Larsen syndrome.
- Those involving, predominantly or exclusively, the hands and feet; these are the distal arthrogryposes. Facial involvement can occur with some of these syndromes, and Freeman-Sheldon “whistling face” syndrome is included.
- *Pterygia syndromes*, in which identifiable skin webs cross the flexion aspects of the knees, elbows, and other joints: Multiple pterygia and popliteal pterygia fit into this group.

Arthrogryposis Multiplex Congenita

Arthrogryposis multiplex congenita is the best known of the multiple congenital contracture syndromes.^{15,16} Although attempts have been made to change the name *arthrogryposis multiplex congenita* to *multiple congenital contractures* or *amyoplasia*, the popularity of the term *arthrogryposis* remains. The cause of arthrogryposis multiplex congenita is unknown. It was initially described in 1841 by Adolf Wilhelm Otto, who referred to his patient as “a human monster with inwardly curved extremities.”¹⁷ It is a sporadic condition, not an inherited one, and arthrogryposis may affect only one member of a pair of identical twins.^{18,19} It has been suggested that teratogens are

Fig. 50-5 PIP joint contractures in the hand of a patient with arthrogryposis. Note the lack of flexion creases at the PIP joints.

a cause of arthrogryposis, but this has not been proved.^{16,20-23} Some mothers of children with arthrogryposis have serum antibodies that inhibit fetal acetylcholine receptor function, raising the possibility that maternal antibodies play a role in the pathophysiology of these fetal antigens.²⁴

Histologic analysis of the muscles in this disorder shows fibrosis and fat between the muscle fibers, with myopathic and neuropathic features in the same muscle biopsy specimen. The peri-articular soft tissue structures are fibrotic. Analysis of the spinal cord shows a decreased number of anterior horn cells in the spinal cord.²⁵⁻²⁷ The pattern of motor neuron loss in specific spinal cord segments correlates with the peripheral deformities and affected muscles, suggesting a primary central nervous pathology in the etiologic factor.²⁸

The diagnosis can be made with clinical examination. The limbs are striking in appearance and position and lack normal skin creases (Fig. 50-5). There may be deep dimples over the joints. Muscle mass is reduced, although infants often have abundant subcutaneous tissue. Affected individuals hold the shoulders adducted and internally rotated, with the elbow more often extended than flexed, and the wrist flexed severely with ulnar deviation. The fingers are flexed and clutch the thumb. The hips are flexed, abducted, and externally rotated. The knees are typically in extension, although flexion is possible; feet often have a clubfoot disorder. Joint motion is restricted. There is a firm, inelastic block to movement. In two thirds of patients, all four limbs are affected equally, but in one third, lower limb deformities predominate; the upper extremities predominate only on rare occasions. There can also be dislocation of the hips.

Fifteen percent of children with arthrogryposis also have an inguinal hernia, although this is because of muscle weakness. Feeding difficulties can be encountered in infancy; these lead to respiratory infections and failure to thrive.²⁹ The face is not particularly dysmorphic.

Radiographs show relatively normal joints, which develop adaptive changes. Electromyograms (EMGs) and muscle biopsies have questionable diagnostic value. A diagnosis of arthrogryposis can be suspected when an absence of fetal movement is detected through prenatal ultrasonography, especially if this occurs in combination with polyhydramnios.²⁰

The natural history of arthrogryposis is not well studied.^{30,31} Some contractures seem to worsen with age, and the joint becomes stiffer. No new joints become involved. At least 25% of patients do not ambulate, whereas many others are limited to walking in the house.³² Patients with arthrogryposis who are very weak as infants remain weak throughout life, and those who appear stronger as infants stay strong. Adult function is more related to education and coping skills than to the severity of the joint contractures.

Treatment

Although there are potential surgical options for each joint, an overview of the total patient is essential when planning surgery. In the upper extremity, the overall goal is motion for self-care.^{13,33-35} Intraarticular changes occur between 4 and 6 years of age; outcomes of joint surgeries are often more successful if they take place before these changes. Realignment osteotomies, however, are usually performed closer to the completion of growth. Early motion and avoidance of prolonged casting may increase joint motion, thereby improving function. Long-term bracing or other assistive devices are often required.¹⁶

Because of joint contractures, the birthing process may be difficult for the infant, resulting in neonatal fractures.³⁶ Physical therapy should not be initiated in the newborn until such fractures are ruled out.³⁷ No studies clearly demonstrate that early mobilization improves patient outcome, but such a program is commonly prescribed and is thought to improve passive range of motion.¹⁶ Fractures may accompany an overly vigorous range-of-motion program.

Most patients do not require surgical procedures of the upper extremity. When evaluating a patient, one must consider an individual joint in the context of the entire upper extremity.^{29,30} Analysis must include an examination of each hand alone and how the two hands work together. Surgery should be undertaken to improve the use of the upper extremities in self-help skills, such as feeding or toileting, and mobility skills, such as pushing out of a chair or using crutches.

The shoulder rarely requires surgery. For the elbow, it is ideal to achieve flexion to 90 degrees from the fixed extended position. However, when both elbows are involved, surgery to increase flexion should only be done on one side at a time. Achieving active elbow flexion is unlikely because of contractures of the joint capsules and muscle weakness. Passive elbow flexion to a right angle is a prerequisite for considering a tendon transfer for active elbow flexion. Restoration of elbow motion by capsulotomy and triceps lengthening has had only fair success, diminishing the likelihood for success when an arthrogryptic muscle is used to motor the joint.³⁸ The triceps brachii and pectoralis are the most commonly used muscles for transfers. Surgery works best in children older than 4 years of age or in those who have at least grade 4 strength of the transferred muscle.³⁹⁻⁴³ Distal humeral osteotomy can be undertaken to place the elbow into flexion and correct some of the shoulder's internal rotation deformity. Osteotomy is usually performed when the patient is about 10 years of age.^{40,44} This surgery should be undertaken in a way that improves hand-to-mouth function. Excessive external rotation of the distal humerus should be avoided.

The hand and wrist are usually flexed and ulnarly deviated.^{45,46} All tissues of the wrist (joint capsule, tendons, fascia, subcutaneous tissue, and skin) are contracted. The ulnar deviation occurs because of unopposed action of the extensor carpi ulnaris, which is usually spared. Numerous techniques to place the wrist in a more neutral position have been described, including proximal row carpectomy, dorsal radial wedge osteotomy, arthrodesis, and resection of a biplanar wedge of midcarpus, with tendon transfer for wrist extension.⁴⁷ Results are unpredictable, and surgery at the wrist should not be considered without first evaluating the extremity as a whole. For example, wrist fusion would remove all wrist motion in a limb that may not have the compensatory abilities of forearm rotation and shoulder abduction. Thus the patient may be left with a less functional limb.

Ulnar-side digits tend to be more involved. PIP flexion deformities rarely respond to physical therapy or surgery. The thumb is flexed and adducted into the palm, and it responds better to surgery than do the other digits. Adductor release and web space deepening with Z-plasty can be performed. Children with arthrogryposis have normal intelligence and usually have a natural ability to learn substitution techniques.

Neuromuscular Disorders: Cerebral Palsy

The cause of cerebral palsy (CP) is unknown; initially, it was thought to be caused by prenatal or early postnatal insults to the CNS. However, this notion has been challenged by data, suggesting that the CNS insults occur much earlier in fetal development. Both the upper and lower extremities can be involved. The typical posture of the upper extremity is characterized by⁴⁸:

- Internal rotation of the shoulder
- Elbow flexion
- Forearm pronation
- Wrist flexion and ulnar deviation
- Thumb adduction or thumb-in-palm deformity
- Finger swan neck or clenched fist deformity (Fig. 50-6)

The prevalence of CP is estimated at 2.5 per 1000 live births, with low birthweight, intrauterine infections, and multiple gestation as the most important risk factors.⁴⁹

Because the cause of CP is unclear and the term may be used to describe conditions caused by several etiologic factors, it can be difficult to diagnose CP in young children. Thus it may be better to think of affected children as having a muscle spasticity disorder. In addition, before 1 or 2 years of age, upper extremity dysfunction may not be apparent. As a child reaches developmental milestones—the development of a pinch between the thumb and index finger, for example—the deficits become easier to diagnose. Because handedness usually does not develop until 18 months, a demonstrated preference for the right or left side before 12 months of age suggests a neurologic insult affecting the nonpreferred side.⁴⁸ Abnormal muscle tone can also suggest a diagnosis of CP, with muscle flaccidity and generalized hypotonia at birth progressing to hypertonia and contractures as the child becomes older.⁴⁸ Persistence of the primitive Moro reflex beyond 6 months, at which point it is normally lost, is another early sign suggestive of CP.⁵⁰

Approximately two thirds of children with CP are mentally impaired, with more than half of those patients moderately or severely mentally disabled.⁵¹ Although the patient's ability to participate in postoperative therapy is important for a favorable outcome, intellectual capacity is only one of many factors that are considered in the management of a CP patient's spasticity.

Four types of CP have been described by Hagberg et al.⁵² These are based on the type of movement disorder: (1) spastic, (2) athetoid, (3) ataxic, and (4) mixed. *Spastic CP* is the most common type, representing more than 80% of cases. Motor spasticity causes muscle imbalance across

Fig. 50-6 Typical posture of a patient with CP. Note the shoulder's internal rotation, elbow flexion, forearm pronation, and wrist flexion.

the joints of the upper and lower extremities, leading to stiffness and eventual contracture. *Athetoid CP* is reported in 10% to 25% of cases and is characterized by slow, withering movements and a lack of voluntary control. *Ataxic CP* is reported in 5% to 10% of cases and is also characterized by a lack of voluntary control; imbalance and tremors are characteristics of the condition. *Mixed CP* is composed of elements of more than one type. The incidence of patients with ataxic and athetoid CP has declined drastically in recent decades because of the recognition that it is caused by maternal-fetal blood cell-antibody mismatch.

Although a specific cause for CP has not been identified, multiple risk factors have been described. These include prematurity, teratogens, genetic syndromes, chromosomal abnormalities, exposure to toxins, intrauterine infections, intracerebral hemorrhage or stroke, complications during labor and delivery, and preeclampsia.⁵³ Early descriptions of CP often cited anoxic brain injury as the cause, but recent reviews of the literature have found that anoxia alone accounts for fewer than 10% of CP cases, and in most cases, a specific cause cannot be determined.⁴⁸

Treatment Goals

Both nonsurgical and surgical treatments are based on maximizing function of the extremity and allowing independence in daily living. In more severe cases, treatment may address hygiene problems from contracted joints. For each CP patient, the treatment plan must be individualized to fit that patient's needs. Perhaps the most difficult decision that a hand surgeon must make is selecting the appropriate patient for surgical intervention. Multiple issues must be considered, such as muscle weakness, spasticity, level of voluntary control, degree of joint stiffness or contracture, sensation, and patient intelligence. Because of this complexity, the hand surgeon must be viewed as a consultant in the overall team management of a CP patient. Input should be sought from all who care for a CP patient: the patient's parents, pediatrician or family doctor, rehabilitation specialist, physical therapist, occupational therapist, and surgeon. A treatment plan with realistic expectations can then be formulated.

Early management of a CP patient includes nonoperative treatments, such as stretching and splinting, which may preserve joint mobility and prevent contractures; however, there is no evidence that this improves patient outcome. Surgery is usually not considered until the patient is older, when independence and level of function can be more adequately assessed. If there is no further improvement or the patient's function worsens despite nonoperative measures, and if the patient can participate in postoperative therapy, surgery is considered.

Patient Selection

The decision to proceed with surgery requires assessment of intelligence, motor control, joint mobility, sensation, support for postoperative care, and level of function. Although many patients with CP are mentally disabled, this should not automatically eliminate a patient from consideration as a candidate for surgery. Optimizing hand position to improve function is an achievable goal, even in a patient with decreased intelligence. However, if mental status is such that participation in postoperative therapy is not possible or the patient demonstrates neglect of the extremity, surgery will not provide much functional benefit. Similarly, if the patient demonstrates a complete lack of sensation, it is unlikely that any surgery would allow the patient to incorporate and use that hand.⁵⁴ In patients in whom addressing long-standing contractures is related more to facilitating hygiene rather than to improving function, intelligence and sensation are less of an issue.

Motor control and joint status must also be assessed. In a CP patient, muscles may be spastic, flaccid, or dyskinetic, such as in the patient who is athetoid. Joint deformity is a result of the muscle imbalance caused by spasticity. Surgery to improve position and function is based on the rebalancing of forces across the joint. This can be accomplished by either reducing the force of the spastic muscles or increasing the force of the antagonist muscles with the use of appropriately selected tendon transfers. Athetosis is considered a contraindication to surgery, because the lack

of voluntary motor control makes muscle rebalancing difficult; this may lead to an unpredictable and unsatisfactory result.

EMG testing may be helpful to identify spastic or flaccid muscles for tendon transfer surgery. Videotaped assessment of range of motion and function of the upper extremity has been found to be a reliable assessment measure.⁵⁵ Therapist-assisted videotaped evaluations can be useful in helping the surgeon develop the optimal treatment plan. Information obtained from repeated viewing of the evaluations adds to the clinical picture provided by the history and physical examination, and it may allow the surgeon to develop a more thoughtful and effective treatment plan.⁵⁵ The videotaped evaluation should include assessment of range of motion of the upper extremity, presence of any joint contractures, and level of function. To assess function, the Jebsen hand function test can be administered, and manual dexterity tasks can be demonstrated.⁵⁵ Both EMG and videotaped assessments should be used as adjuncts to a thorough history and physical examination in patient selection for surgery.

Nonsurgical Treatment

Splinting is often prescribed to prevent the development of joint contractures. The use of splints is somewhat controversial, because decreased spasticity and prevention of contractures have not been shown with splinting.⁵⁶ In addition, splinting may actually enhance the deformity by placing a hyperexcitable muscle under tension and increasing muscle tone.⁵⁴ Nevertheless, splints are used to improve hand position and may help to perform activities of daily living. If used at night when the child is completely relaxed, splints may help to prevent contractures.⁴⁸

The use of botulinum toxin (Botox) to decrease motor spasticity in a CP patient is becoming more widely reported.⁵⁷ It is more commonly used for lower extremity spasticity. The goal of botulinum toxin therapy is to improve function by decreasing muscle tone. However, the long-term effectiveness of botulinum toxin in a CP patient has not been shown, and indications for use have not been clearly established. In the treatment of ankle equinus contractures, the addition of botulinum toxin to a serial casting regimen led to an earlier recurrence of spasticity, contracture, and equinus during gait when compared with the casting-only group of patients.⁵⁷

In our experience, Botox treatment works best in younger children without fixed contractures or in those who have limitations in function caused by dynamic spasticity with active motion. This is the same group of patients in whom splinting may produce the most functional improvement.

Surgical Treatment

Surgical treatment is based on addressing the patient's motor spasticity and subsequent muscle imbalance, which are responsible for producing the characteristic joint deformities. Surgical options to correct the imbalance by weakening the spastic muscle include muscle denervation, muscle or tendon lengthening, and muscle release. Surgical options include tendon transfers and tenodesis to correct the imbalance by augmenting the power of a muscle opposing the spastic muscle. If the surgical goal is to place the hand in a more functional position to facilitate skin care, joint fusion is an option.

Selecting which patients will benefit from surgery is more challenging than deciding on the type of surgery. Surgery should only be undertaken to correct a specific functional defect. In our experience, most CP patients do not require surgical treatment.

The typical posture of the upper extremity is characterized by:

- Shoulder internal rotation
- Elbow flexion
- Forearm pronation
- Wrist flexion and ulnar deviation
- Thumb adduction or thumb-in-palm deformity
- Finger swan neck or clenched fist deformity

Patients will present with variable severity at multiple joints. No one technique can be universally applied to all CP patients, and treatment plans must be individualized based on careful functional assessment and input from all members of the multidisciplinary team. If a patient is considered a good surgical candidate, corrective surgery is planned to address multiple joints in as few visits to the operating room as possible to minimize the anesthetic risk and postoperative morbidity.

Elbow flexion contracture is a common finding in CP patients because of the spasticity of the biceps, brachialis, and flexor-pronator muscles. Patients may have difficulty with feeding and self-care because of the position of the hand when the elbow is fixed in flexion. Transfers to a chair, keyboarding, and using assistive devices at tabletop level may be more difficult with an elbow flexion contracture. In more severely debilitated patients, a flexion contracture may lead to hygiene problems and chronic wounds in the antecubital fossa. Fractional lengthening or step cuts allow lengthening of the biceps and brachialis tendons.^{54,58,59} Release is achieved through a zigzag or lazy-S incision in the antecubital fossa. The median nerve, brachial artery, and biceps and brachialis tendons are identified. Surgical release should be done cautiously, because it may weaken elbow flexion to the point where the extremity is in a more extended but less functional position for feeding and self-care activities. In contractures that have been present for a long time, joint capsule release may also need to be done to improve elbow position.

Pronation is the usual posture of the forearm because of the spasticity of the pronator muscles and weakness of supination. Excessive forearm pronation affects self-care, feeding, and use of a keyboard or communication board. Techniques to correct the pronation imbalance and place the forearm in a more neutral position include pronator fasciectomy, pronator lengthening, and pronator rerouting. Gschwind and Tonkin⁶⁰ described pronator quadratus fasciectomy for mild contracture. The pronator teres can also be lengthened by transecting it or doing a step cut at its insertion on the radius.⁶¹ The tendon ends are sutured together with the forearm in maximal supination. If supination is weak or absent, the pronator teres can be released with a strip of periosteum off its insertion, rerouted through the interosseous membrane and around the radius, and then reinserted onto the radius to serve as a supination force against the pronator quadratus.^{60,62}

The wrist is typically flexed in a CP patient because of the spasticity of the wrist flexors, which are often combined with weak extensors. A flexed wrist interferes with activities of daily living, such as eating and drinking, self-care, dressing, and typing on a keyboard. Grip strength is decreased if the wrist is in a flexed position. Passive range of motion to the neutral position must be achieved before rebalancing surgery is considered. Wrist flexion contracture can be improved by lengthening the flexors, releasing the wrist capsule, and performing tendon transfer to augment wrist extension. Tendons that serve as good donors for transfer in non-CP patients may not be good sources in a CP patient because of a global neuromuscular disorder. Wrist extension must be evaluated independent from and in conjunction with finger extension.

Procedures that can be used to correct wrist flexion contracture include flexor fasciectomy, flexor tenotomy, flexor tendon lengthening, and superficialis-to-profundus transfer. In mild cases of contracture, the fascia can be excised through a longitudinal incision on the palmar aspect of the forearm. Tenotomy of the flexor carpi ulnaris (FCU) can be done just proximal to its insertion on the pisiform to allow more wrist extension.⁶³ If tenotomy of the FCU does not produce significant improvement, tenotomy of the flexor carpi radialis may be considered.⁴⁸ However, Tonkin and Gschwind⁶³ considered a lack of voluntary control of the radial wrist extensor a contraindication to tenotomy of the FCU and did not recommend tenotomies of both wrist flexors. Flexor tendon lengthening by step cuts or fractional lengthening is considered when full active and passive extension of the fingers is demonstrated only when the wrist is flexed 20 degrees or more. Improvement in grip may be seen in flexor tendon lengthening, because it may place the wrist in a more extended position. In more severe cases of flexor tendon contracture—those in which improvements in hygiene and appearance are more achievable than improvement in functional grasp—*superficialis-to-profundus* (STP) transfer can be done.⁶⁴ In this procedure, the

superficialis tendons are divided proximal to the wrist, and the profundus tendons are cut near the musculotendinous junction. The proximal cut ends of the superficialis tendons are then woven into the distal cut ends of the profundus tendon. With this transfer, a tenodesis effect is produced, with the fingers first extended during wrist flexion and then flexed with wrist extension.

Weak wrist extension can be improved with tendon transfer, usually of the FCU. The FCU is a contributing factor in a flexion contracture. Release of the FCU and transfer to the extensor carpi radialis brevis (ECRB) tendon accomplishes two goals in rebalancing the forces across the wrist by weakening flexion and strengthening extension. The FCU is the preferred donor for extension of the wrist in the CP patient, because it is typically available and usually provides a reliable result.⁶⁵ The technique of FCU-to-ECRB transfer involves releasing the FCU tendon from the pisiform and then rerouting it around the ulna to the ECRB tendon on the radial side. The FCU muscle is dissected free from surrounding fascia to allow adequate mobilization for the tendon weave. This mobilization allows proper alignment of the musculotendinous unit and maximizes the force of the transfer.

Before correcting the imbalance at the wrist by augmenting extension, the effect of the transfer on finger extension must be considered. The pronator teres and the brachioradialis can be transferred to the ECRB for active wrist extension. In a CP patient, these transfers are less reliable and may produce a permanently extended wrist, thereby decreasing grasp power and impeding release of the hand. Range of motion of the digits must be assessed with the wrist. If full passive extension of the digits is possible and weak release of the digits is the main problem, then FCU-to-extensor digitorum communis (EDC) transfer should be considered to augment active digital extension. If passive extension is limited, however, then fractional lengthening of finger flexors should be considered. In the severely contracted wrist, release of all the wrist flexors (FCU, flexor carpi radialis, and palmaris longus) may not be enough to place the wrist in a neutral position, and wrist fusion will be required.

The thumb often demonstrates an adduction contracture, with the thumb metacarpal adducted against the palm or second metacarpal. The imbalance of forces can also produce *metacarpophalangeal* (MP) or IP joint instability. Spasticity of both the adductor pollicis and the first dorsal interosseous muscles, as well as the weakness of the thumb abduction, also contribute to the characteristic deformity (Fig. 50-7). Surgical treatment of the thumb addresses the adduction contracture and joint instability. Release of the contracture is achieved by a dorsoulnar incision to expose the first dorsal interosseous muscle and adductor pollicis. The fascia of the first dorsal interosseous muscle is excised, and in some patients, the muscle may need to be released

Fig. 50-7 Thumb adduction contracture in a patient with CP. Spasticity of the adductor pollicis and first dorsal interosseous muscles, weakness of thumb abduction, MP joint instability, and tightness of the first web space contribute to this deformity.

from its insertion on the first metacarpal. The adductor pollicis is lengthened by detaching it in step-cut fashion and then suturing it to itself. More palmar dissection allows release of the adductor pollicis origin from the third metacarpal.⁶⁶ The first web space skin contracture can be lengthened by Z-plasty. Shortening of the abductor pollicis brevis (APB) tendon or transfer of an active motor, such as the brachioradialis, can be done to augment weak thumb abduction. To improve thumb extension, the extensor pollicis longus (EPL) can be transected at the MP level, passed through a separate dorsal wrist incision, rerouted through the first dorsal compartment, and then sutured back into place at the MP joint. Less common than adduction contracture is the thumb-in-palm deformity, which is produced by a spastic flexor pollicis longus (FPL) and weak thumb extension: EPL, extensor pollicis brevis (EPB), and abductor pollicis longus (APL).⁶⁷ Options to correct this imbalance include FPL lengthening and flexor digitorum superficialis (FPL; fourth digit) transfer to the EPL.⁶⁸

The characteristic finding of the fingers is the swan neck deformity, typically caused by intrinsic muscle spasticity, although the long extensors can be shortened in a long-standing wrist flexion contracture. Because the swan neck deformity can be improved with corrective surgery for the wrist flexion contracture, surgery to correct the swan neck deformity is usually delayed until the effect of the wrist rebalancing surgery is known. Surgical options to address the swan neck deformity include superficialis tenodesis, intrinsic muscle denervation, tendon transfers, lateral band tenodesis, PIP palmar plate arthroplasty, and PIP joint fusion.⁶⁹⁻⁷¹

Postoperative management for tendon transfers involves immobilization for 4 to 6 weeks, followed by exercises to increase range of motion. Night splints are worn for approximately 3 months after surgery. Splints may also be used beyond the 3-month period to provide support or prevent new deformity.

Inflammatory Disorders: Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis (JRA) is the most common connective tissue disease occurring during childhood, affecting approximately 60,000 to 250,000 individuals.⁷² JRA is characterized by chronic synovial inflammation and hyperplasia, which lead to edematous and hyperemic tissue grossly. On the microscopic level, there is infiltration by lymphocytes and plasma cells. Clinically, this continued inflammation may result in progressive periarticular erosions and joint destruction. Compared with the adult form of rheumatoid arthritis (RA), JRA has a much milder course, with approximately 50% to 70% of cases going into remission.⁷³ There are three types of JRA: (1) systemic onset (Still's disease), (2) polyarticular, and (3) pauciarticular.

Clinical features of *Still's disease* include:

- Intermittent high fevers
- Erythematous macular rash
- Generalized lymphadenopathy
- Hepatosplenomegaly
- Leukocytosis
- Anemia
- Uveitis
- Arthralgia
- Myalgia
- Transient arthritis

Rheumatoid factor (RF) and antinuclear antibodies (ANA) are usually not found. Of those patients with Still's disease, 25% have severe chronic arthritis.⁷² Approximately 40% of patients have the polyarticular form of JRA. *Polyarticular JRA* most resembles adult RA and is also the

most likely to progress to adult RA. It is characterized by multiple joint involvement and occurs more frequently in females than in males. Most patients with polyarticular JRA are not RF positive, but those who are RF positive are more likely to develop severe chronic arthritis as adults.⁷²

The remaining 40% of cases are *pauciarticular JRA*, which is characterized by the involvement of four or fewer joints within the first 6 months of the onset of symptoms. Two distinct groups are affected. The first group is characterized by female patients younger than 6 years of age who are usually ANA positive and RF negative. Joint involvement of the lower extremity and iridocyclitis are more common in this group. Other joints may become involved later in the course of the disease. The second group is older and predominantly male, with an association with the HLA-B27 haplotype. These patients are ANA and RF negative. The lower extremity joints are also involved in this group.⁷³

To establish a diagnosis of JRA, other inflammatory conditions, such as septic arthritis, osteomyelitis, inflammatory bowel disease, and malignancy, should be ruled out. Unlike adults, RF may not be found in JRA patients or may be seen only in older pediatric patients. The absence of RF in a child with clinical signs of JRA does not exclude the diagnosis.

The number of affected joints and the severity are variable. In the hand, the characteristic findings are loss of flexion and the presence of radial deviation at the MP joints and a loss of IP joint flexion. In an adult, the characteristic finding is ulnar deviation and loss of extension at the MP joint.⁷³ At the wrist, the typical presentation is ulnar deviation and loss of wrist extension. There may also be ulnar shortening up to 9 mm, but this does not correlate with ulnar deviation or MP radial deviation.⁷² Proliferative synovitis may lead to joint edema and stiffness and subsequent loss of flexion. Local synovitis can also cause epiphyseal overgrowth or undergrowth around affected joints and may result in premature physal closure. The resultant bony deformity is affected by the duration of the disease. If the onset of disease occurs before skeletal maturity, growth of the hand may be diminished.

Radiographic findings can demonstrate early signs of disease with periarticular soft tissue swelling, juxtaarticular osteoporosis, and periostitis. Radiographic findings of late disease include destruction of joint, cartilage, and bone; bony fusions; and growth anomalies, such as premature epiphyseal closure.⁷² Bony change is most commonly seen at the knee and wrist. A shortened ulna and abnormal growth of the fourth and fifth metacarpals from premature physal closure may be seen. There may also be narrowing of the intercarpal, radiocarpal, and carpometacarpal joints, diminished size of the small bones of the hand, or premature ossification of the wrist bones.

After the diagnosis of JRA is made and the subtype is identified, treatment goals are directed at minimizing symptoms, preventing deformity, and preserving function. As with other chronic conditions, care is supportive rather than curative. A multidisciplinary approach involving the pediatrician, rheumatologist, physical therapist, occupational therapist, orthopedist, and hand surgeon is advocated.

Nonsurgical Treatment

Nonsurgical treatment is directed at relieving symptoms, maintaining good joint position, preserving function, facilitating activities of daily living, and preventing deformities. First-line therapy includes antiinflammatory medication, physical therapy, and splinting. As with adults, medical therapy can be the most effective way to control disease. Pharmacologic options include aspirin, NSAIDs, gold, D-penicillamine, methotrexate, sulfasalazine, and steroidal agents. NSAIDs are usually not prescribed on a regular basis until a patient is 14 years of age.⁷² Resting splints may provide comfort and help to place the hand in a more functional position. With improvements in pharmacologic management, the need for surgery has substantially declined. Novel therapies on the horizon may decrease the need for surgery even further in the future.

Surgical Treatment

In general, surgery of the upper extremity is rarely indicated in the JRA patient and is considered only after the use of nonoperative measures.⁷⁴ Reconstructive procedures commonly used in the adult RA population are not indicated in younger patients because of the risk of epiphyseal arrest resulting from injury to the growth plate. Surgery can be considered during the late teen years, when growth is completed and symptoms warrant surgical intervention. Patients who are RF positive are more likely to need surgery to alleviate symptoms.⁷⁴ Postoperative improvement in a JRA patient results from excision of proliferative synovitis and better joint motion. Affected joints are either stabilized or reconstructed.

The following issues should be considered before surgery: the pattern of joint involvement, the degree of skeletal immaturity, the timing of interventions, and the risk of surgery causing epiphyseal arrest. The goals of surgery are to alleviate pain, retard progression of disease, improve function, improve appearance, and maintain growth and motion.⁷² At the wrist and MP joints, synovectomy can be done to decrease the inflammatory activity at the joints and prevent its sequelae of joint destruction and fixed deformity. Hand and wrist involvement in the JRA patient has been reported in up to 59% of patients.^{73,75} Synovectomy is usually considered after 6 months of persistent synovitis and failure of medical management. Candidates for surgery usually present with swollen, painful, boggy joints, decreased motion, and radiographic evidence of joint destruction. As with surgery in the hand, there is a risk of inducing more swelling, stiffness, and decreased motion postoperatively. This risk must be weighed against the potential benefit of the surgery to relieve pain, which is reported in the population.⁷²

There are numerous well-described procedures to address the problems of the small joints of the hand: boutonnière deformity, swan neck deformity, palmar plate laxity, dorsal capsule tightness, and collateral ligament shortening. The most common procedures in the hand for the JRA patient are MP joint capsulectomy for MP joint contracture, sublimis resection for PIP joint contracture, and ulnar collateral ligament (UCL) tightening. Indications and techniques for these surgeries are the same as in an adult RA patient, although they are performed on a much less frequent basis. Joint replacement is not advocated in a JRA patient because of the limited life expectancy of the implant and the high demands of younger, more active patients.

Hematologic Disorders: Fanconi Anemia

Fanconi anemia (FA) is an autosomal recessive disorder of bone marrow dysfunction that is associated with multiple birth defects, including upper extremity anomalies. The preaxial structures—the thumb and radius—are the most commonly affected and represent both cosmetic and functional deformities. The most common anomaly seen in patients with FA is thumb hypoplasia and radial dysplasia, followed by thumb hypoplasia alone and radial polydactyly.⁷⁶ Other clinical features include short stature, café-au-lait spots, red cell macrocytosis, and renal, genitourinary, and cardiac anomalies. It is critical to distinguish FA from thrombocytopenia absent radius (TAR) syndrome. Hematologic dysfunction in FA worsens with time, so surgery should be considered early in life; with TAR syndrome, the hematologic deficits improve over time, and therefore surgery should be delayed. One can easily differentiate between the two conditions, because patients who have TAR always have a fully formed thumb.

A patient with a thumb anomaly may present to a hand surgeon without any workup for FA. If other clinical features of FA are present, the hand surgeon may initiate the evaluation of FA by referring the patient to a hematologist or pediatrician for additional testing. Early diagnosis allows proper management of the hematologic disorder, appropriate timing of any elective surgery before the advent of bone marrow failure, and genetic counseling for the family. The median age at which hematologic complications occur is 8 years, but there is a wide range.⁷⁷

The goal is to maximize hand function and promote independence within the context of a chronic hematologic disorder. If the underlying blood disorder is under control or goes into remission, surgery can be considered. One of the goals of the treatment team may be to complete any surgeries to improve function of the hand before the development of any hematologic problems.

Because there is a wide spectrum of presentation, there is no single best approach or technique to manage these patients. The treatment plan must be individualized, taking into consideration the patient's overall function, the potential benefit of the procedure, and input from physical and occupational therapists.

After the decision is made to proceed with surgery, hematologic issues must be addressed. Blood work is done to see whether any coagulopathies are present and to check for evidence of thrombocytopenia, leukopenia, and anemia. In the patient with FA, laboratory tests may help to decide whether to delay surgery or whether it is safe to proceed. There should be a preoperative assessment by both the physical therapist and occupational therapist. The workup may also include investigations for cardiac, renal, and genitourinary anomalies, if indicated.

Involvement of the thumb and radius is variable, ranging from hypoplasia to absence. Evaluation and treatment of thumb hypoplasia are discussed in Chapter 43. Radial deficiency can present as a short radius (type I), a hypoplastic radius (type II), a partially absent radius (type III), or a radius that is completely absent (type IV) (Fig. 50-8). Complete absence is the most common

Fig. 50-8 Clinical appearance of total absence of the radius in a 5-year-old child. The presence of a thumb determines whether this condition is more likely Fanconi anemia (in which case the thumb would be hypoplastic or absent) or TAR syndrome (the thumb would be present).

Fig. 50-9 Radiograph of a 10-month-old patient with total absence of the radius. The thumb is present.

type of radial deficiency; in the FA patient, complete absence of the radius may also occur with complete absence of the thumb.

The typical posture in partial or complete absence of the radius is severe radial deviation of the wrist, stiff fingers, lack of forearm rotation, and limited elbow flexion (Fig. 50-9). Stretching is started at an early age, and splints are used to maintain a straight alignment. If the wrist continues to deviate radially despite nonoperative measures, then surgery is considered to improve function. Centralizing the wrist involves placing the carpus on the ulna. Although this provides a correction, recurrence is common.

KEY POINTS

- A multidisciplinary approach is needed for treatment of these complex patients.
- The entire upper extremity—not just the hand—must be assessed in these children to ensure proper potential positioning for effective use.
- The fragile skin in epidermolysis bullosa makes it susceptible to blistering and scarring, even with minor trauma. Great care must be taken with splinting, rehabilitation, and the administration of general anesthesia.
- Unfortunately, EB often progresses to irreversible pseudosyndactyly, mitten and cocoon hand, joint contractures, and muscle atrophy.
- Surgical goals in EB hand reconstruction are directed at positioning digits in a more functional position.
- Arthrogryposis is a physical finding of joint contractures at birth; these contractures can be seen in several syndromes and conditions.
- The cause of cerebral palsy remains unclear.
- The surgical management of CP is focused on maximizing function, allowing increased independence and use, and facilitating hygiene. Each surgery must be individualized to the child's physical, psychosocial, and environmental needs.
- Release of the thumb adduction contracture can be very rewarding—it may increase hand function significantly.
- The treatment goals for patients with juvenile rheumatoid arthritis are focused on relieving symptoms, preventing ongoing deformity, preserving or increasing function, and improving appearance.

Toe-to-Hand Transfers in Children

Patrick L. Reavey • Neil F. Jones

oe-to-hand transfer is one of the triumphs of modern surgery and has been applied successfully to restore hand function in both adults and children after traumatic loss or congenital absence of digits. In children with congenital differences, toe-to-hand transfer has revolutionized hand reconstruction, and the lives of these children and their parents have been transformed by this marvel of modern medicine. The technique has been refined over the past five decades and is currently used throughout the world, primarily in major academic institutions and hospitals. It is a procedure with many risks and requires a dedicated team of microsurgeons, pediatricians, intensive care nurses, pediatric nurses, pediatric occupational hand therapists, and psychologists.

Nicoladoni¹ successfully completed the first toe-to-hand transfer in a child in 1898 using a staged pedicle transfer by joining the hand and foot together for 4 weeks. Other surgeons repeated the technique, but because of potential complications such as sciatic nerve palsy, pressure sores, and deep venous thrombosis, the concept of a one-stage free microvascular digital transfer was investigated. In 1964 Buncke et al² experimentally transferred a toe to the hand of a monkey and opened up the possibility of using this technique in humans. In 1966 Yang Dong-Yue of Shanghai First Medical College performed the first microvascular transfer of a second toe to the hand in a human.³ Cobbett⁴ was the first to transfer a great toe based on the plantar arterial system to reconstruct a thumb, and Buncke et al⁵ transferred the great toe based on the first dorsal metatarsal and dorsalis pedis arterial system. The pioneering work of these surgeons provided the basis for the widespread expansion and evolution of this reconstructive technique. Today many different centers have reported successful transfer of the great toe and second toe, simultaneous double toe transfer, staged double toe transfer, and vascularized joint transfers.⁶⁻⁵²

Relative to adults, toe-to-hand transfer is performed less frequently in children. However, with refinement in microsurgical techniques, the indications in children are increasing, and the success rate is similar to adults. Toe transfers have been used to reconstruct children's hands with missing digits as a result of trauma, congenital constriction ring syndrome, transverse deficiencies, cleft hand, symbrachydactyly, and even radial club hand.^{3-11,12-41,45,50} Toe-to-hand transfer is usually reserved for children with severely aplastic hands with absence of multiple digits. Although toe transfer has been reported for the treatment of isolated thumb hypoplasia, the benchmark remains pollicization of the index finger.^{22,37,40-42,44,53} The great toe and all lesser toes, either individually or together, have been transferred to the hand in the pediatric population.^{19,23,39}

Microsurgical toe transfer requires meticulous technique and a keen eye for aesthetics. It combines the fields of plastic surgery, orthopedic surgery, and neurosurgery in a way that is unparalleled in any other surgical endeavor. It is an important technique in the armamentarium of hand surgeons, but it will undoubtedly undergo continued refinement to optimally replicate the appearance and complex function of a human thumb or finger.

CONGENITAL HAND DIFFERENCES

The incidence of a child being born with absent or hypoplastic digits is approximately 1 in 6800 births.¹⁹ The diversity of congenital hand differences may at first seem overwhelming; however, they can usually be divided into two broad categories: transverse and longitudinal deficiencies and then further subdivided based on the presence or absence of particular digits. Transverse deficiencies may present as a true transverse arrest, congenital constriction ring syndrome, or symbrachydactyly (atypical cleft hand).^{1,7,18} Longitudinal deficiencies may present as thumb hypoplasia, radial club hand, cleft hand, or more rarely, ulnar club hand. Numerous anatomic and embryologic classification systems have been described for each of these processes. However, Jones and Kaplan⁵⁴ have described a unifying classification system based on the morphologic and radiographic appearance of congenital differences⁵⁴ (Fig. 51-1). This system provides a useful algorithm for approaching congenital hand reconstruction with either conventional or microsurgical techniques. Only the phenotypes R1 (distal to the carpometacarpal joint), R2, R3, R4, R5, U4R1, and occasionally C3R1U1 (at the proximal phalangeal level) are candidates for microsurgical reconstruction with toe-to-hand transfers.

In general, the anatomic structures in the hand are more developed in children with congenital constriction ring syndrome (see Fig. 51-5, *A* and *B*) than in children with hypoplasia, true transverse arrest, and symbrachydactyly^{3,19} (see Figs. 51-9, *A* and *B*, 51-10, *A* and *B*, and 51-11, *A* and *B*). Children with longitudinal deficiencies (see Fig. 51-8, *A* through *C*) may lack adequate proximal tendons and nerves necessary to power the transfer and may be more appropriate candidates for reconstruction by transfer of adjacent digits.^{7,49} In the monodactylous form of symbrachydactyly, a relatively consistent anatomy with the presence of carpal bones but loss of the central metacarpal rays is expected. The border metacarpals are usually present, but the thumb is often hypoplastic, unstable, and short or totally absent. Remnants of the fingers may be represented as small nubbins with or without nails.¹⁹

Symbrachydactyly is sometimes difficult to distinguish from simple transverse absence or transverse arrest. The small nubbins with nail remnants seen in symbrachydactyly are usually replaced in transverse arrest by small protuberances, dimples, or large fleshy bags of skin without skeletal contents in transverse arrest.⁷ The digital nerves and arteries may be very hypoplastic in an adactylous or monodactylous hand, requiring more proximal dissection to larger digital nerves for nerve repair and to the radial or ulnar artery for vessel anastomoses.

Fig. 51-1 Classification system for congenital absent digits: morphologic and radiographic spectrum. **A**, Radial deficiencies. **B**, Ulnar deficiencies.

Continued

Fig. 51-1, cont'd C, The radiographic spectrum of central deficiencies. Only the phenotypes R1 (distal to the carpometacarpal joint), R2, R3, R4, R5, U4R1, and occasionally C3R1U1 (at the proximal phalangeal level) are candidates for microsurgical reconstruction with toe-to-hand transfers.

PREOPERATIVE ASSESSMENT

The initial assessment of a child with a congenital hand difference begins with careful history-taking, listening to the parents, and allowing them to express their understanding of their child's condition and their hopes and expectations for treatment. It has been shown that the parental response to a child born with a congenital anomaly resembles the bereavement response.^{44,55} Parents must cope with their own sense of loss, as well as the obligation to direct the treatment of their child. Some authors recommend that the parents and child meet with a clinical psychologist before considering a toe-to-hand transfer, and it has been shown that psychological counseling may play an integral role in decision-making in pediatric hand surgery.^{21,25} Additionally, several parents of children who have undergone a toe-to-hand transfer are willing to speak with families considering the operation. This provides an opportunity for the parents to ask questions about the entire reconstructive process and assuage some of their concerns in a way a medical professional might not.

Surgeons should obtain information regarding any significant past medical history that may indicate whether a child has a syndrome and whether anyone in the family has a similar hand condition. They should attempt to assess the functionality of the hand in a detailed physical examination. Observing very young children at play may be sufficient. Children should be examined with their shirt off to check for spinal and shoulder girdle abnormalities (Poland syndrome). The presence or absence of the thumb and its functionality are recorded. The thumb carpometacarpal joint is assessed, because it is critical to the success of a toe-to-thumb transfer.⁹ The presence or

absence of the radiocarpal joint and the number and size of the metacarpal bones is determined. Dimpling of the skin over the ends of the metacarpals with hand motion may indicate the presence of tendons that are tethered beneath the skin.

The feet are examined at the initial assessment. Congenital differences of the lower extremities may coexist with upper extremity differences.¹³ If possible, the foot may be brought close enough to the hand so that the parent and child can visualize what a transferred toe may look like. Parents usually greatly appreciate the chance to look at preoperative and postoperative molds and/or photographs and videos of toe transfers.

Preoperative imaging studies include plain radiographs of both hands and wrists and plain radiographs of both feet. The presence of metacarpals and of a thumb carpometacarpal joint is assessed; if this joint is absent, the surgeon may need to perform a pollicization of an adjacent metacarpal to serve as the base for the transferred toe. In cases in which the carpal and/or metacarpal bones have not yet ossified, an MRI may be useful.¹⁸
